Abstract. Aim: The aim of this study is to present the first total number of tested children in the Federation of Bosnia and Herzegovina and the number of children with a positive sweat test. During the study, we determined the number of ill children, the median age of children with cystic fibrosis, the date of initial diagnosis, and an average amount of chloride in the sweat. Materials and methods: The study was a retrospective one, conducted at the Department of Pulmonology, Pediatric Clinic of the University Clinical Center of Sarajevo. Results: In the period from March 2003 to December 2014, we tested 625 children. 351 children were from the Sarajevo Canton and 272 children from other cantons. Female children were more affected than male children, in the ratio of 1:1.105. The average age of female children was 4.19±4.26 years, and the average age of male children was 2.15±3.11 years. The median concentration of chloride in the sweat measured by the sweat test was 103.05±21.29 mmol/L for male children, and 96.05±28.85 mmol/L for female children. Conclusion: Most of children in the Federation of Bosnia and Herzegovina have ΔF508 gene mutation. In the post-war period, we started using the sweat test. Male children with CF tend to live longer than female children.

Key words: Cystic fibrosis, sweat test, pilocarpine iontophoresis, chloride, sodium

1. INTRODUCTION

Cystic fibrosis (CF) or mucoviscidosis is a multisystem inflammatory disorder where the primary cause of morbidity and mortality is pulmonary destruction, characterised by chronic inflammation, bacterial colonisation and frequent exacerbations [1,2].

CF is an autosomal-recessive disease caused by mutations in the CF transmembrane conductance regulator (CFTR) protein at the chromosome 7q31.2 (CFTRΔF508). The mutation is a deletion of the three nucleotides that comprise the codon for phenylalanine at position 508. Mutations of the CFTR gene affecting chloride ion channel function lead to dysregulation of epithelial fluid transport in the lung resulting in cystic fibrosis [3,4]. In the United States approximately 30,000 individuals have CF, and in Canada 4,000 [8]. In the European Union, 1 in 2000-3000 newborns is found to be affected by CF [5,6,7]. CF occurs in one of every 3,200 live Caucasians, and in 1 of every 15,000 live African American births, 1 of every 31,000 live Asian Americans births [2,8].

In normal conditions, CFTR regulates the normal absorption of sodium ions (Na+) from the lumen of the channel gland, by controlling the function of neighbouring epithelial sodium channel (ENaC). In CF this control is missing, which leads to excessive absorption of Na+ in the epithelial cells. Inhibit secretion of Cl- and Na+ hyperabsorption lead to the withdrawal of water from the lumen of the secretory canals of glands and secretion in them remains dehydrated and viscous and difficult to be removed by normal mucociliary mechanisms. This leads to obstruction of the airway lumen and a suitable basis for the development of pathogenic microorganisms [1,2,9].

In the thick layer of dense and tenacious secretions airway gradually create anaerobic conditions, which encourages bacteria to adjustment, especially pseudomonas, with the formation of alginate and mucous form of growth [10].

Cystic fibrosis is a chronic progressive disease that affects multiple organ systems and whose manifestations related primarily to the development of chronic lung disease and malnutrition [1,2,9].

Diagnosis is made by finding elevated levels of chloride in the sweat test. Sweat test is used to measure chloride and sodium levels in sweat. They can be

* amina_selimovic@hotmail.com
performed at any time from 1 week of age, but adequate sweat volumes may not be obtained before 6 weeks of age. If there is any clinical suspicion of CF, a sweat test should be arranged, even if the patient has had newborn screening, since approximately 5% of CF cases are not detected by newborn screening. Sweat electrolyte values in adults are often higher than children and need to be interpreted by an expert. The sweat glands are made to produce sweat with a mild chemical called pilocarpine and a little electricity (pilocarpine iontophoresis) [11,12].

Sweat-testing involves application of a medication that stimulates sweating (pilocarpine). To deliver the medication through the skin, iontophoresis is used to, whereby one electrode is placed onto the applied medication and an electric current is passed to a separate electrode on the skin. The resultant sweat is then collected on filter paper or in a capillary tube and analyzed for abnormal amounts of sodium and chloride. People with CF have increased amounts of sodium and chloride in their sweat [11].

The reference ranges of sweat chloride that are currently accepted for the diagnosis of CF in infants up to and including 6 months of age are: equal to or less than 29 mmol/L means CF is very unlikely, 30-59 mmol/L means that CF is possible, greater than or equal to 60 mmol/L means CF is likely to be diagnosed. The reference ranges of sweat chloride that are currently accepted for the diagnosis of CF in people older than 6 months of age are: equal to or less than 39 mmol/L means CF is very unlikely, 40-59 mmol/L means that CF is possible, greater than or equal to 60 mmol/L means CF is likely to be diagnosed [1,11].

The test is carried out by collecting sweat from pilocarpine iontophoresis in two or more occasions and chemical determination of the concentration of chloride. The conditions other than cystic fibrosis, which are associated with elevated concentrations of sweat electrolytes include malnutrition, adrenal insufficiency, glycogen storage diseases, anorexia, celiac disease, hypothyroidism, hypoparathyroidism, nephrogenic diabetes insipidus, ectodermal dysplasia, atopic eczema, and congenital metabolic disease. Most of these errors are caused by using unreliable methodology, irregular way of collecting sweat, technical errors and misinterpretation of results [1,2,11].

2. Patients and Methods

We retrospectively analyzed all hospital records at the Pediatric Clinic of University Clinical Center of Sarajevo between March 2003 and December 2014. We included all resident patients of the Federation of Bosnia and Herzegovina, consisting of Canton Sarajevo and 9 other cantons. We selected all patients with positive sweat test, and also recorded age, gender, date of initial diagnosis, amount of chloride in the sweat test, the number of patients in Federation of Bosnia and Herzegovina.

3. Statistical Analysis

Statistical analysis was performed using SPSS 20.0 (SPSS, Chicago, IL, USA). In the analysis of the difference between the observed group was used Pearson’s test, chi-square test, Ficher’s exact test, Yates’ chi-square test with correction for small samples (with tables in which the number of cells in less than 5), and Student’s t-test and One-way analysis of variance (ANOVA), depending on the type of data. The results of these statistical tests were considered statistical significance at p <0.05 or at the level of 95%. The analysis was performed using the statistical package SPSS Statistics IBM v21.0 (Chicago, Illinois, USA).

4. Results

During the 11-year period we registered 40 cases of cystic fibrosis. Nineteen were male children and twenty-one female children. The median age in all patients (n=40) with cystic fibrosis was 3.22±3.85 years (interquartile range 0 to 15 years). The mean age for male children (19/40) was 2.15±3.11 years, and for female children (21/40) 4.19±4.26 years. There was no significant age difference (t=2.912; df=39; p=0.096) between male and female children.

The total number of sick children (male and female) from March 2003 to December 2014 was 40, 19 male children and 21 female children. Analysis of the frequency of gender according to the year of diagnosis of cystic fibrosis showed that the largest number of children fell ill in 2011, seven. The minimum number of detected children was in 2010, two children (Table 1). There was no statistically significant differences in male compared to female children by the year of discovery CF, (γ² = 9.801; DF = 22; p = 0.458).

Pilocarpine iontophoresis or “sweat test” is a method used to measure an average amount of chloride in the sweat of children. An average amount of chloride in the sweat in male children (19/40) was 103.05±21.26 mg/L (interquartile range 60 to 131 mmol/L chloride); and in the female children 89.71±22.95 mmol/L (interquartile range 60 to 128 mmol/L chloride). The total average amount of chloride in sweat at all affected children was 96.05±28.89 mmol/L (interquartile range 60 to 131 mmol/L chloride). The lowest measured amount of chloride, which was enough to confirm the diagnosis of cystic fibrosis in male and female children was 60 mmol/L in sweat, while the maximum amount of chloride in male children in sweat was 131 mmol/L, in the female children 128 mmol/L. According to the analysis there was no statistically significant difference (t=3.612; DF=39; p=0.046) between the average amount of chloride by gender (Figure 1).

Children from the Federation of Bosnia and Herzegovina consisting of Canton Sarajevo and other cantons, are tested at the Pulmonary Department of the Pediatric Clinic at the University Clinical Center Sarajevo. The total number of tested children in the Federation was 625 for the period 2003-2014 years, while the number of children tested just in the Sarajevo Canton was 351, and from others cantons 272 children (Figure 2).

Table 2. The evidence of infected children with P. aeruginosa (2008-2014)

| Year       | Canton Sarajevo | Other cantons | Total |

5. DISCUSSION

This study shows for the first time the number of children suffering from CF in the Federation of Bosnia and Herzegovina from March 2003 to December 2014. Advanced diagnostics led to the diagnosis in the early stages of the disease which greatly facilitates the further treatment of patients and thus prolongs the life span. Seventy years ago patients died in the first year of life most of malabsorption and diarrhea. Today, patients experience the second and third decade, and life expectancy is determined by duration of pulmonary disease. Survival of patients with CF has dramatically improved since the disease was discovered, 70 years ago. Progressive pulmonary disease is leading to morbidity and pulmonary arrest, and the average life expectancy of people with 37.4 years, 37 years for women and 40 years for men (13,14). The average life expectancy in Federation of BiH is 14 to 17 years old. Progress in the length of life of patients is the result of many new improvements in treating disease. Progress
has been made in the diagnosis of CF and the introduction of neonatal screening. It is possible to act on intracellular events and encourage, correct or potentiate multiple mutant CFTR forms with defects in CFTR channel gating, (15,16,17). In the final stage lung disease is available and lung transplantation, individuals with CF must have both lungs replaced because there maining lung might contain bacteria that could infect the transplanted lung (18). Although the lifespan moved from childhood to adult age, patients are still faced with an abundance of therapeutic needs, and their doctors with a new pathology. The challenge is identifying new manifestations and complications of the disease as well as the actual carrying out of treatment. A special, more a problem in the treatment of patients with CF becomes a problem of economic sustainability of therapy.

During the first decade of life of CF patients, Staphylococcus aureus and Hemophilus influenzae are the most common bacteria isolated from the sputum, but in the second and third decade of life, Pseudomonas aeruginosa is the prevalent bacteria.

In cystic fibrosis (CF) lung occupy a special place, because it in most patients with CF are determined by the quality and length of life. The lung is an organ that before birth is not affected by the changes, but soon after birth becomes a place of chronic infection and inflammation. The main goal of therapy in CF is focused primarily on the lungs, and that means delay and reduce the damage and thereby contribute to the quality and duration of life expectancy of CF patients. Therapy of CF today are not causal, or untreated primary disorder, but is based on the treatment of a number of consequences that illness affects many organ systems.

6. Conclusion

Children born with CF today have a greater chance of living longer, thanks to early diagnosis and multidisciplinary approach to treatment, where children may benefit from treatment with mitigation damaged ionic transport with medications such as inhalers, mucolytics, antibiotics, anti-inflammatory drugs, and methods of cleaning the airways.

Male children with CF tend to live longer than female children with CF, and there is no gender (“sex gap”). Socioeconomic status may affect the length of life of the sick and environmental factors, exposure to cigarette smoke, air pollutants.

Children with CF have a majority of ΔF508 genetic mutation. The most difficult patients in the post-war period were from the Central Bosnia Canton, while lately the number of children from Canton Sarajevo with manifestations of harder lung obstruction has risen but without growth deformation and changes in radiogram like in post-war children. Whether this can be explained by new mutations of children with CF or not, time will tell.

Due to the progression, cystic fibrosis is inseparably associated with infection of lungs. P.aeruginosa is the most common bacterial species involved in respiratory tract infection in CF, while Burkholderia have also been identified as causing infection of CF patients.
