Azurite, Cu$_3$(CO$_3$)$_2$(OH)$_2$, has been considered an ideal example of a one-dimensional diamond chain antiferromagnet. Early studies of this material imply the presence of an ordered antiferromagnetic phase below $T_N$=1.9 K while magnetization measurements have revealed a 1/3 magnetization plateau. To the best of our knowledge, no corroborating neutron-scattering results have been published to confirm the ordered magnetic moment structure. We present recent neutron-diffraction results which reveal the presence of commensurate magnetic order in azurite which coexists with significant magnetoelastic strain. The latter of these effects may indicate the presence of spin frustration in zero applied magnetic field. Muon spin rotation reveals an onset of short-range order below 3 K and confirms long-range order below $T_N$.

DOI: 10.1103/PhysRevB.81.140406 PACS number(s): 75.50.Ee, 61.05.fm, 65.40.De, 76.75.+i

Despite the burgeoning volume of data on the natural mineral azurite and its magnetic properties, the precise details of its spin-ordered state and the microscopic exchange couplings remain contentious issues. Recently, strong magnetoelastic coupling has been observed in azurite indicating significant interdependence of structural and magnetic degrees of freedom. This effect is reminiscent of the spin-Peierls cuprate system CuGeO$_3$ (Ref. 2) in which the distortion is thought to be due to competing antiferromagnetic (AFM) interactions. In contrast, the structural distortion in azurite coincides with a transition to a three-dimensionally ordered AFM state.

Azurite, Cu$_3$(CO$_3$)$_2$(OH)$_2$, is a quasi-one-dimensional (1D) system and the first realization of the distorted diamond chain. Here, Cu$^{2+}$ ions form a triangular arrangement of spin S=1/2 moments which are arranged as chains propagating along the crystallographic b axis. The diamond chain model has been extensively studied, with the distortion implied by three inequivalent exchange couplings, $J_1 \neq J_2 \neq J_3$. This model affords a host of exotic phases and quantum phase transitions, including exotic dimer phases and $M=1/3$ fractionalization.

Azurite has a monoclinic crystal structure (space group $P2_1/c$) with room-temperature lattice parameters $a=5.01$ Å, $b=5.85$ Å, $c=10.3$ Å, and a monoclinic angle, $\beta=92.4^\circ$. An NMR study initially revealed the AFM phase transition at $T_N=1.86$ K (Ref. 15) while magnetization measurements have indicated the presence of a distinct 1/3 magnetization plateau. Long-range magnetic order was also confirmed by electron spin resonance measurements revealing AFM resonance modes below 1.9 K. Additional studies, including muon spin resonance ($\mu$SR), indicated that the magnetic phase transition at $T_N$ is of second order.

Recently, there has been some controversy over the effective dimensionality of azurite. Ab initio density-functional calculations have suggested that there is sizeable magnetic exchange between the diamond chains. Inelastic neutron-scattering measurements exhibit dispersive magnetic excitations along the chain, indicating that significant magnetic exchange is present in this direction. Subsequent measurements of the dynamical spin correlations in both directions perpendicular to the chain have revealed no dispersion. Thus the dynamics appear well defined by an effective one-dimensional model.

Now, while the study of spin dynamics can yield estimates of effective magnetic couplings within azurite, a detailed study of the static spin arrangement reveals much about the strength of the microscopic exchange interactions and spin anisotropy. This motivated the current survey of the magnetic ordering transition in azurite.

Here we present measurements from both single crystal and polycrystalline samples using a variety of neutron-diffraction methods as well as $\mu$SR measurements. We present the first observation of magnetic order from which we have determined the magnetic propagation vector of the commensurate structure. Importantly, we also observed significant lattice distortions in the single-crystalline material indicating a strong magnetoelastic coupling in the lattice. This lattice strain is consistent with the results of high-resolution thermal-expansion measurements to be published in more detail elsewhere.

The samples used in this study were derived from the same high-quality single crystal of Cu$_3$(CO$_3$)$_2$(OH)$_2$. A cube was cut with length ~5 mm for the single-crystal neutron measurements. A smaller crystallite, oriented along the b axis, was used for the thermal-expansion measurements. For this, the resolution was greater than $\Delta l/l=10^{-10}$, where l is the sample length. Smaller crystallites were crushed thoroughly for the powder-diffraction studies. The powder experiments were performed using the E9 diffractometer at the...
Helmholtz Zentrum Berlin (HZB) (neutron wavelength $\lambda = 1.798$ Å) at temperatures $T=5$ and 1.28 K. Single-crystal neutron diffraction has been carried out using the E1 triple-axis spectrometer (TAS) at HZB (neutron wavelength $\lambda = 2.43$ Å). The sample was mounted with a horizontal $a^*b^*$ scattering plane within a $^3$He insert to ensure good thermal stability below $T_N \sim 1.9$ K. Further single-crystal neutron measurements were performed on the flat-cone diffractometer, E2, also at HZB at 2 temperatures, 1.4 and 2.5 K. The neutron wavelength was fixed at $\lambda = 2.4$ Å to ensure greatest resolution from the thermal neutrons. Finally polycrystalline $\mu$SR measurements were carried out at the Swiss Muon Source of the Paul Scherrer Institut PSI, Villigen, using the $^3$He installation at GPD (MUE1). Transverse-field (TF) experiments with a field of 50 G (50 GTF) were performed as a function of temperature in order to systematically follow the magnetic behavior close to $T_N$.

The powder neutron-diffraction results are summarized in Fig. 1. These data were successfully refined using the FULLPROF program with the monoclinic crystal structure reported in the Refs. 12–14 [solid (blue online) line in Figs. 1(a) and 1(b)]. The lattice parameters found from the refinement of the 1.28 K data set were $a=5.002(1)$ Å, $b=5.825(1)$ Å, $c = 10.342(1)$ Å, and a monoclinic angle, $\beta = 92.21(1)^\circ$. The error values $\chi^2 = 2$ and $R_{Bragg} = 4.8$ indicate the high quality of the fits.

FIG. 1. (Color online) Powder neutron-diffraction spectra of azurite at (a) 5 K and in the AFM phase at (b) 1.28 K. Tics indicate structural Bragg-peak positions, (+) represent experimental data. The solid line on the data shows the result of the refinement and the difference between refinement and fit is plotted at the bottom of each graph. In (c) the difference between the spectra taken at 1.28 and 5 K is plotted.

The temperature evolution of the scattering intensity was observed over the quadrant in reciprocal space bounded by the points (000), (300), (030), and (330). For every Bragg peak which was measured in this quadrant we found a steep increase in intensity at $T_N$. The temperature dependence of the intensity of the (120) structural Bragg peak is illustrated in Fig. 2. A rough calculation suggests that any magnetic scattering contribution from the copper atoms would be about 1/20th of the nuclear scattering. Thus the additional 80% intensity on the (120) peak cannot be magnetic in origin.

Fitting the temperature dependence of the scattering intensity to the scaling expression, $(T_N-T)^{\beta}$ we obtain the transition temperature $T_N = 1.88$ K for our sample, in good agreement with the value obtained from bulk experiments. However, for the critical exponent, $\beta$ we find a value of 0.06 which is extraordinarily small, again implying that the $T$ evolution of the additional Bragg-peak intensity is not magnetic in origin.

In conjunction with the change in intensity of the structural Bragg peaks it was also found that the $b$-lattice parameter decreases significantly below $T_N$. The inset of Fig. 2 exhibits the thermal-expansion data measured along the $b$ axis in zero field. The uniaxial thermal-expansion coefficient $\alpha(T) = -1/dl/dT$ reveals a $\lambda$-like anomaly at $T_N$ reflecting the character of the second-order phase transition. The extraor-
thermal-expansion data of CuGeO$_3$ where sizable frustration

tural distortion at $T \sim 1.9$ K we conducted powder $\mu$SR ex-
For temperatures above about 3 K the sample signal consisted purely of a weakly damped Gaussian typical for a field distribution due to nearby nuclear moments. Meanwhile a strongly damped component appears for temperatures below 3 K which is related to a magnetically or-
This can be traced in TF and also zero applied field (details will be reported in Ref. 26). As seen from Fig. 3 the normalized magnetic fraction, as deduced from the strongly damped contribution in 50 GTF, rises when lowering
The increase in magnetic signal below 3 K is reminiscent of the maxima observed in susceptibility and heat capacity observed around 5 K and 4 K, respectively. There it was related to the onset of correlations between monomers. We interpret our data below 3 K with
FIG. 4. (Color online) Intensity distribution in reciprocal space taken from low-temperature single-crystal neutron diffraction of Cu$_3$(CO$_3$)$_2$(OH)$_2$. These plots show a cut along the $ab$ plane with all information out of the plane binned. White stripes indicate regions where no data was collected. The circle indicates an additional Bragg peak occurring at (1 1/2 1) at temperatures below $T_N = 1.9$ K. The two high-intensity concentric circles visible in both diffraction patterns are powder-diffraction lines from the sample mount.
short-range order due to correlations between monomers in-
duced via the coupling through the dimers which finally leads to the ordered phase below $T_N$. From these results we can conclude that the magnetic order becomes long range below 1.8 K. The apparent discrepancies in the onset tem-
peratures for short-range order, as obtained by $\mu$SR, specific heat and susceptibility, reflect the different time windows of these techniques.
To find magnetic ordering wave vectors of complex mag-
netic structures an effective method is three-dimensional (3D) reciprocal-space mapping. The E2 flat-cone diffracto-
meter, equipped with two-dimensional position sensitive de-
tectors, accesses a large portion of $k$ space, with Miller indi-
ces from $-3 < h < +3$ and $0 < k < +3$ covered in the $a^*b^*$ plane and $-\frac{2}{10} < l < +\frac{3}{10}$ in the $c^*$ direction.
On cooling below $T_N$ magnetic Bragg peaks were ob-
erved at the positions $(\pm \frac{1}{2} \frac{1}{2} 0), (\pm \frac{1}{2} \frac{1}{2} \frac{1}{2})$, and $(\pm \frac{1}{2} \frac{1}{2} \frac{1}{2})$. The most intense of these is the $(\frac{1}{2} \frac{1}{2} \frac{1}{2})$ peak, circled in red in Fig. 4 implying that the magnetic peaks do not lie within the $ab$ plane. This explains their absence from the TAS data and indicates an AFM structure with a magnetic unit cell double the size of the structural cell in each crystallographic direction. The other magnetic peaks, $(\pm \frac{1}{2} \frac{1}{2} \frac{1}{2})$ and $(\pm \frac{1}{2} \frac{1}{2} \frac{1}{2})$, are too weak to be observed with the intensity scale in Fig. 4.
TFS taking the symmetry of the crystallographic space group into account we can make some deductions about the mag-
netic structure of azurite. We consider only the monomer copper sites to be of importance in the magnetic ordering as the Cu$^{2+}$ dimer sites have only small local spin polarization and will not act independently. The size of the spin moment on the dimer site is related to the staggered field of the neigh-
boring copper sites. The larger the spin gap of the dimer unit, the less influential the staggered field is in inducing a net spin moment on the dimer sites. Ohta and Rule both found the size of the dimer spin gap to be large compared to the magnitude of the staggered field. Based on the propagation vector of $(\frac{1}{2} \frac{1}{2} \frac{1}{2})$ and using the SARAh-REPRESENTATIONAL ANALYSIS program we find two possible representations for the spin basis vectors, shown in Table I. From the basis vec-
TABLE I. The basis sets associated with the irreducible representations of the space group $P2_1/c$ and propagation vector $k = (\frac{1}{4}, \frac{1}{2}, \frac{1}{4})$. The basis sets give the relative phases of monomer spins at the two different Cu sites $Cu(1) = (000)$ and $Cu(2) = (\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ in fractional lattice positions.

| IR  | $Cu(1)$                          | $Cu(2)$                          |
|-----|----------------------------------|----------------------------------|
| $\Gamma_1$ | $[e^{i\pi/2}e^{-i\pi/2}e^{i\pi/2}]$ | $[e^{-i\pi/2}e^{i\pi/2}e^{-i\pi/2}]$ |
| $\Gamma_2$ | $[e^{i\pi/2}e^{-i\pi/2}e^{i\pi/2}]$ | $[e^{-i\pi/2}e^{i\pi/2}e^{-i\pi/2}]$ |

It appears that the monomer sites on neighboring chains along the $c$ direction should be oriented perpendicular to each other. Such a noncollinear configuration may suggest the presence of Dzyaloshinskii-Moriya interactions in the system.

Susceptibility measurements\(^{18}\) indicate that the easy axis $x'$ is at approximately 55° from the $c$ axis in the $a$-$c$ plane. Note that in both of the representations, $\Gamma_1$ and $\Gamma_2$, the $x$ and $z$ components of the spins transform identically. We would therefore expect to be able to couple the $x$ and $z$ components of the spins such that the spins are constrained to lie in the $x'y$ plane. Further investigations will be required to obtain the precise orientation of the spin moments and the magnitude of the ordered magnetic moment.

It is curious that both magnetic ordering and structural distortion have been observed only in the single crystal and not in the powder neutron-diffraction data. It is likely that the ordered magnetic moment in azurite is rather small which caused any magnetic scattering intensity to be obscured by incoherent scattering. It is also possible that the small grain size in the polycrystalline sample could have inhibited observation of the lattice strain. The single-crystal TAS results have finally revealed the strong magnetostriction leading to a contraction of the $b$ axis below $T_N$. This structural distortion must be taken into account when estimating the microscopic magnetic exchanges with regards to the details of the superexchange pathways as it may imply a significant alteration of the Cu-O-Cu bond angles with respect to those of the high-temperature structure.

Despite often being described as a good example of a 1D Heisenberg chain antiferromagnet, the low-temperature properties of azurite appear to be more complex than first thought. The observation of a 3D ordered AFM phase implies that a simple 1D Heisenberg model is not sufficient to describe the system at low temperatures. Instead it seems necessary to consider further magnetic interactions such as interchain superexchange pathways and anisotropic exchange interactions such as Dzyaloshinskii-Moriya couplings.

The low-temperature lattice parameters of azurite have been found from powder neutron-diffraction results and provide essential information for electronic-structural calculations.\(^{30}\) The neutron results have also revealed the commensurate nature of the long-range magnetic ordering in a single crystal. $\mu$SR results verify that magnetic order is also present in the polycrystalline material while lattice strain in the single crystal is associated with the onset of the magnetically ordered phase.

In conclusion, neutron scattering and $\mu$SR spectroscopy have revealed evidence of a magnetically ordered phase in azurite. From these results a propagation vector of $(\frac{1}{4}, \frac{1}{2}, \frac{1}{4})$ best describes the scattering of the ordered state which is reached via a second-order phase transition. Further to this, a large structural strain has been observed in azurite, coinciding with the transition to 3D AFM long-range order.
