Wastewater treatment consists of removing or decreasing a number of hazardous substances such as chemicals and biological pollutants [3]. The selection of the treatment approaches is strongly influenced by their characteristics and compositions. Various wastewater treatment approaches have been used such as chemical, physical, and biological approaches [3]. Advanced oxidation, electrocoagulation, and flocculation are the most common methods of physical and chemical treatment whereas suspended or activated sludge process is an example of the biological treatment that is widely applied [4]. Although these conventional methods have successfully treated various wastewater sources, they have some limitations. The physical and chemical methods face the problems of high-energy requirements, incomplete removal of heavy metals, generation of secondary pollutants,
complex operation, and high cost [4–6], and the biological method deals with the problems of the easy washout and low biomass concentration [4].

The use of microalgae to treat wastewater is currently of global interest due to its advantages. On the one hand, microalgal cells have the ability to uptake nutrients such as phosphorus, nitrogen, and ammonium as well as heavy metals to reduce BOD in wastewater [7–10] and also simultaneously capture the carbon dioxide from the atmosphere during photosynthesis decreasing the greenhouse gaseousness [11, 12]; on the other hand, the wastewater can be considered as a cheaper nutrient source for the growth of microalgae. However, at the current state, the biological nutrient removal technologies, including the use of microalgae, have not been competitive in the wastewater industries. The main issue contributes to the high cost of recovery of the treated effluent and biomass using current dewatering methods such as centrifugation and filtration [11]. To overcome the issue, the existing cell suspended method can be replaced with the immobilization method. The advantages of immobilization over the suspended method have directed researchers to discover in detail the system [3, 4, 13, 14]. Not only can cell immobilization simplify the separation process, but it also offers other advantages such as higher cell density, higher productivity, better cell stability, and biomass recirculation [3, 4, 13, 15, 16]. One of the most important parts in the immobilization technique is selecting a suitable carrier. As the common carriers such as alginate and polyacrylamide face some drawbacks like low stability and toxicity, respectively [13, 17], finding and using a new carrier with ideal characteristics (i.e., nontoxic, stable, and cheap) can solve existing problems. One of the ideal candidates applied for the immobilization is zeolite. Zeolites are inorganic materials that are resistant to microbial degradation and also cost-effective [4, 18]. The application of zeolites is in agriculture, catalysis, building industries, energy, and treatment of water streams [1, 19–45]. In addition to these common applications, they have been used as a carrier for biomass immobilization [3, 15, 46–55] and applied in different areas such as production of high-value products [15, 46, 47, 49, 50, 53] and metal/nonmetal removal [5, 48, 51, 52, 54, 55]. Various kinds of microorganisms have been used for the immobilization onto zeolites such as bacteria [5, 15, 49–54] and yeast [46, 47].

This article reviews the immobilization technique, biomass immobilization onto zeolites as special carriers, and algal immobilization. Furthermore, the potential application of zeolite as an ideal carrier for algal immobilization has been discussed.

2. Immobilization

Immobilization is defined as a process of cell attachment and/or cell inclusion to or into a carrier volume as a support [13, 56]. Cell immobilization has a number of advantages over suspended cells shown in Table 1. Immobilized systems have been applied in various applications such as the production of noncontaminant energy [57, 58], wastewater bioremediation [13], toxicity measurement [58, 59], metabolite production [58, 59], and stock culture management [3].

### Table 1: Advantages of cell immobilization over suspended cell.

| Advantages of immobilization       | References          |
|-----------------------------------|---------------------|
| Simplifying biomass harvesting    | [3, 4, 13]          |
| Higher cell density               | [3, 4]              |
| Enhancing operational stability   | [3, 4]              |
| Avoiding cell washouts            | [3]                 |
| Increasing cell resistance to unfavorable factors (temperature, acidity, and toxic compounds) | [13] |
| Occupying less space              | [3]                 |
| Easier to handle                  | [3]                 |
| Using repeatedly                  | [3, 14]             |

2.1. Types of Immobilization. The process of microorganism immobilization can be done by various mechanisms, including adsorption, covalent bonding, cross-linking, encapsulation, and entrapment in a matrix [3, 4, 13, 18, 50, 59–65]. Table 2 shows various types of immobilization method along with their advantages and disadvantages. According to Eroglu et al. 2015 and Godlewksa-Żyłkiewicz et al. 2003, the most common immobilization methods are cell attachment and cell entrapment [3, 64]. In immobilization via adsorption, the attachment is done without using intermediate molecules while, in the covalent attachment, the “bridge-molecule” is used for functionalization of the support [63]. In the entrapment method, cells are captured into a three-dimensional gel lattice. This kind of supports can be either natural or synthetic [3, 59, 60, 65]. The method is often used for capturing microorganism in suspended solution. Due to the porous structure of polymers, different kinds of metabolites can be easily diffused through the matrices [4, 18].

2.2. Operational Modes of Immobilization. The immobilization process can be done in two operational modes: passive and active [13, 57]. The passive mode is based on the natural ability of the microorganism to attach to the natural or synthetic carriers (solid or gel-like surfaces) and grow on them [4, 13, 57, 59]. The mechanisms for the carrier attachment involve physical (electrostatic and hydrophobic interactions)
Table 2: Immobilization methods of microorganisms and their advantages and disadvantages (Figures adapted from [4, 62]).

| Method               | Definition                                                                 | Advantages                                                                 | Disadvantages                                                                 | Figure | References          |
|----------------------|-----------------------------------------------------------------------------|----------------------------------------------------------------------------|--------------------------------------------------------------------------------|--------|---------------------|
| Adsorption           | Based on physical interaction between biomass and support surface          | (i) Simplicity                                                            | (i) Relative weakness of the adsorptive binding forces                         |        | [4, 18, 50, 62]     |
|                      |                                                                            | (ii) Minor influence on biocatalyst conformation                          |                                                                              |        |                     |
|                      |                                                                            | (iii) No need for chemicals utilization                                    |                                                                              |        |                     |
| Covalent bonding     | Based on bonding reaction of some groups (e.g. —COOH or —NH₂) at the surface of microorganism | (i) More stable than adsorption                                           | (i) Involves toxic bifunctional reagents                                      |        | [4, 13, 18, 62, 63] |
|                      |                                                                            |                                                                           | (ii) Decreasing bioactivity of microorganism                                 |        |                     |
| Cross-linking        | Based on linking biomacromolecules to each other by covalent bonds using multifunctional reagents (e.g. glutaraldehyde) | (i) Simple method                                                         | (i) Very difficult to control                                                 |        | [4, 18, 62]        |
| Encapsulation        | Based on encapsulating microorganisms into synthetic or natural polymers   | (i) Natural polymers                                                       | (i) Diffusion limitation                                                      |        | [4, 18, 62]        |
|                      |                                                                            | (ii) Synthetic polymers                                                    |                                                                              |        |                     |
| Entrapment in a matrix | Based on microorganism entrapment in porous polymer support              | (i) Natural polymers (Higher nutrient/product diffusion rates and more environmentally friendly) (ii) Synthetic polymers (More stable) | (i) Transfer limitations                                                      |        | [3, 4, 18, 59, 61, 62] |
and chemical (covalent bond formation) [4, 13]. The most common electrostatic interactions involved in the initial stage of adsorption are ionic and hydrogen bonding [4]. In contrast, in the active mode, there is not any dependence on the natural ability of cells for the attachments [13] and the mechanisms for the carrier attachment are covalent bonding, cross-linking, and inclusion of cells into the carrier [4, 13, 57]. In addition, the carrier type is either synthetic or natural [13, 57].

2.3. Ideal Carrier for Immobilization. One of the important parts in the immobilization process is selecting a suitable carrier. According to Vasilev et al. 2016 and Das and Adholeya 2015, there are two types of carriers that can be used for cell immobilization: natural and synthetic [4, 13]. The ideal carrier for cell immobilization has to fulfill some characteristics such as porous structure, light weight, being inert, nonbiodegradable in the test condition, and nontoxic, no inhibition, and allowing mass transfer. Also, the carrier should have high stability, including chemical, mechanical, and biological, be environmentally friendly and cheap, and provide an irregular, rough surface for colonization [4, 13, 66, 67]. To date, various supports have been used in cell immobilization, including organic and inorganic supports. Organic supports have higher absorbability and larger forms of reaction groups like amino, hydroxyl, and carboxyl than inorganic supports [4]. Alginate, agar, carrageenan, polyacrylamide (PAM), and polyvinyl alcohol (PVA) are some of the examples of organic carriers. Another form of carrier materials is inorganic such as clay, activated charcoal, and zeolite. These materials have some characteristics, including resistance to microbial degradation, suitable thermostability performance, and cost-effectiveness [4, 18].

3. Biomass Immobilization onto Zeolites

3.1. Zeolite. Zeolite is a ceramic catalysts, agriculture, building industries, energy, and removal process of oil, ammonium, metal ions, etc. from water streams [1, 19–45]. The ratio of Si/Al in zeolite structure is used to indicate the hydrophobicity of zeolite. A higher ratio of Si/Al indicates a higher degree of hydrophobicity and lower ion-exchange capacity [70]. In addition to common applications of zeolite, another significant application of the material is for biomass immobilization as suitable carriers.

3.2. Zeolite-Immobilized Biomass and Its Applications. Many advantages can be offered by zeolite-immobilized biomass. According to Weiß et al. 2010 and Mullan et al. 2003, zeolites are ideal carriers for immobilization. In addition, the carrier type is either synthetic or natural cross-linking, and inclusion of cells into the carrier [4, 13, 57]. Ideal Carrier for Immobilization.

Zeolites have various applications in catalysis, agriculture, building industries, energy, and removal process of oil, ammonium, metal ions, etc. from water streams [1, 19–45]. The ratio of Si/Al in zeolite structure is used to indicate the hydrophobicity of zeolite. A higher ratio of Si/Al indicates a higher degree of hydrophobicity and lower ion-exchange capacity [70]. In addition to common applications of zeolite, another significant application of the material is for biomass immobilization as suitable carriers.
Table 3: Various types of zeolite-immobilized biomass and their applications.

| Type of zeolite | Immobilized biomass | Applications | Findings | References |
|----------------|---------------------|--------------|----------|------------|
| Clinoptilolite  | Acidogenic biomass  | Copper and iron removal | Biosorption capacity of 28.65 mg/g copper and 34.72 mg/g iron | [48] |
| Mg-modified zeolite | Lactobacillus rhamnosus | L (+) lactic acid production | Overall productivity of 1.41 g/L/h | [15] |
| Zeolite         | Actinobacillus succinogenes | Succinic acid production | Productivity of 2.83 g/L h | [49] |
| Zeolite (type 13X) | Lactobacillus rhamnosus | Lactic acid production | Productivity of 1.69 g/L | [50] |
| Chilean natural zeolite | Bacterial microorganism | Ammonium removal | Adsorption capacity of 2.7 mg/g | [51] |
| Zeolite 13X     | Arthrobacter viscosus | Chromium removal | 100% removal | [52] |
| Trace metal activated zeolite | Hemicellulolytic bacteria | Biogas production | Methane increase by 53% | [53] |
| Zeolite NaY     | Escherichia coli | Chromium, cadmium, iron, nickel removal | 100% removal for iron | [5] |
| Natural zeolite | Arthrobacter viscosus | Chromium removal | 18% removal | [54] |
| Natural zeolite | Anaerobic microorganisms | Anaerobic treatment of Wastewater | COD removal efficiencies as high as 90% | [55] |
| Natural zeolite | Saccharomyces cerevisiae | Ethanol fermentation | Ethanol concentration 2% (w/v) | [46] |
| Zeolite         | Saccharomyces cerevisiae | Alcoholic fermentation | Productivity of 35.6 g ethanol/L.h | [47] |

were used as a support for microorganism immobilization in anaerobic reactors resulting in stabilizing and optimizing process efficiency [53, 71]. Also, the immobilized biomass obtained after the process can be used for other applications as it has a high worth. It can be considered as biomass enriched feed [15] and useful for animals [50]. In addition, Djukić-Vuković et al. 2013 reported that a simple cell separation in the fermentation area and cell reuse in repeated batch cycles were achieved by immobilization [50]. Also, Figueroa-Torres et al. 2016 reported that the acidogenic biomass immobilized in clinoptilolite is a low-cost biosorbent for copper and iron removal [48]. This is an important finding that further can make the whole process more feasible for industrial applications. There are several factors interfered in the attachment process between biomass and zeolite. As reported by Macario et al. 2007, zeolites showed a significant property towards the immobilization process, including hydrophobic or hydrophilic behavior, acid or base character, chemical and mechanical resistance, great morphology, a total surface area, and easy water dispersion/recuperation. Also, the researchers reported that zeolites included a great number of Si-OH groups that play key roles in the adsorption process [63]. According to Djukić-Vuković et al. 2013 and Kubota et al. 2008, the surface of zeolite can adsorb biopolymers such as proteins, nucleic acids, RNA, and DNA in a selective manner as well [50, 70]. Due to these reasons, zeolites can adsorb microorganisms on their surfaces, and they can be used as an efficient [50] and potential [72] carrier in the process of biomass immobilization. On the other hand, the surface of microorganisms is full of various components, such as polysaccharides [70]. Exopolysaccharides (EPS) can have a protective role in unfavorable conditions and act as adhesives for interactions with various substrates and also as a promoter for cell aggregation and biofilm formation [50, 73]. There is a possibility that EPS may contribute to the process. According to Pazos et al. 2010 and Lameiras et al. 2008, under stress conditions in a diluted medium, the biofilm formation can increase the production of EPS, resulting in the formation of coherent biofilm with a powerful adhesion to the carrier surface [52, 54]. Djukić-Vuković et al. 2013 used Lactobacillus rhamnosus for immobilization onto zeolite and they reported that the bacterium produced EPS and formed a sticky layer on the surface of the microorganism; hence, it aided the immobilization process [50]. Table 3 shows various types of zeolite-immobilized biomass and their applications.

3.2.1. Production of High-Value Products. The zeolite-immobilized biomass can be used for the production of some metabolites such as acids [15, 49, 50] and alcohols [46, 47]. In a research done by Shindo et al. 2001, natural zeolite abilities were compared with glass beads for the immobilization and alcohol fermentation. The results showed that the immobilization capacity and alcohol fermentation activity of natural zeolite were 2- and 1.2-fold higher than
those of glass beads, respectively [46]. Also, the modified (or activated) zeolite as a biomass support can increase process yields. Weiß et al. 2010 used hemicellulolytic bacteria for the immobilization on trace metal activated zeolite and their results showed an increase of methane by 53% compared to without immobilization. The study also found that the modification of zeolite by trace metal elements such as iron, magnesium, cobalt, and nickel favors microorganisms to be grouped in small microcolonies and supply cofactors in the enzyme biosynthesis process [53]. One of the main purposes of the immobilization technique, as mentioned before, is recycling the immobilized materials. The more the number of repetitions is, the higher efficiency and low cost will be. Djukić-Vuković et al. 2016 used Mg-modified zeolite as a support for Lactobacillus rhamnosus immobilization and their results showed that the attachment of biomass on zeolite was strong and stable resulting in a continuous colonization during four cycles [15]. In addition, Shindo et al. 2001 used natural zeolite as a support for Saccharomyces cerevisiae in a bioreactor and reported that no breakage of the carrier during continuous alcohol fermentation for over 21 days was achieved [46]. Also, Macilio et al. 2007 found that the enzyme immobilized on zeolitic supports could catalyze some cycles, but it continuously leached from the support [63].

3.2.2. Metal Removal. The main pollutant removal mechanisms by microorganisms include assimilation, biodegradation, and biosorption [4]. Assimilation is the process of nutrient ingestion (e.g., carbon, nitrogen, and phosphorus) from wastewater by microorganisms and using them for their growth. Biodegradation is explained as the decomposition/chemical disbanding of organic materials through microorganisms/microbial aggregates aerobically and/or anaerobically. Biosorption is a phenomenon in which microorganisms can adsorb heavy metals and organic and inorganic materials via various processes, including complexation, flocculation, ion exchange, etc. [4, 74]. There are various significant factors that interfere in the biosorption process. Figueroa-Torres et al. 2016 mentioned that there are two factors that are significantly contributing during the biomass selection as potential biosorbent, including its availability and price [48]. During the removal of pollutants, all the processes of assimilation, biodegradation, and biosorption simultaneously happen [4, 74]. In the process of metal uptake by biomass, various factors are responsible for the nature of the process and determination of the binding mechanism, including chemical groups (e.g., structural polysaccharides, amino and phosphate groups in nucleic acids, carboxyl groups in proteins, etc.) and also solubility and polarity [3, 4, 54, 74–76]. Quintelas et al. 2009 reported that the functional groups existing on the biomass (Escherichia coli), including carboxyl, hydroxyl, and phosphate groups, were probably the main binding sites in the biosorption process. It was also observed that the metal affinity to the biofilm pursued the arrangement of Fe(III) > Ni(II) > Cd(II) > Cr(VI). This preference may be described on the basis of metal ion electronegativity and cation/anion state [5]. In addition, various physicochemical forces such as covalent bonding, van der Waals bonding, ion exchange, and dipole/dipole interactions are other factors that can interfere in ion uptake on the adsorbent [3, 76].

As suspended biofilm alone cannot be applied especially in the continuous treatment process and also zeolite, in turn, cannot retain all the metals, there is a need to evaluate the synergistic effect between biosorption ability of biomass and retention capacity of zeolite [5]. To date, several types of microorganisms have been used for the immobilization onto zeolites in the biosorption area [5, 48, 51, 52, 54, 55, 66, 77–80]. The process efficiency of biosorption is dependent on operational parameters such as biomass concentration and pH [52]. Pazos et al. 2010 used a bioreactor, including a biofilm supported on zeolite 13X and their results revealed that the biomass concentration and pH were the key variables for the metal ion removal. Also, the process efficiency was improved by adjusting biomass concentration and pH values. They successfully reached up to 100% removal of the metal ion under the optimized conditions [52]. Using other supports along with zeolite can also be effective in increasing the process yield. Lameiras et al. 2008 used minicolumns including Granular Activated Carbon (GAC) and a natural zeolite as a support for biomass immobilization and found that the combination of GAC and zeolite columns covered with biofilm gave better performance of 42% removal than individual GAC (19%) and zeolite (18%) [54]. Another interesting issue with the system is whether the zeolite by itself is effective in the process efficiency or just acts as a support for biomass. Monge-Amaya et al. 2013 used aerobic biomass biofilm for the immobilization on untreated clinoptilolite zeolite and Energy-Dispersive X-ray Spectroscopy (EDS) analysis showed that the metal ion (copper) was not detected in the treated zeolite and only absorbed by the biomass. Therefore, they concluded that zeolite had functioned as a support for the biomass [78]. There is a prominent challenge in water stream treatment which is faced with a presence of a number of metal ions in real samples. If there is any competition between them and a special removal of the adsorbent, it is an interesting issue to discuss among researchers. Figueroa-Torres et al. 2016 reported that although the predicted amount for the maximum biosorption capacity of copper raised from 28.23 in a single system to 35.46 mg / g SSV in a binary system, the presence of both ions (copper and iron coexistence) in the medium diminished the actual biosorption capacity of biomass [48]. The mechanism of metal ion sorption by zeolite-immobilized biomass can be represented by some isotherm models, including Langmuir [5, 48], Sips [5], and Toth [5], and kinetic models such as the pseudo second-order type reaction [48, 52]. Consequently, zeolite-immobilized biomass can be considered as a promising low-cost biosorbent for metal ion removal [48].

3.2.3. Nonmetal Removal. The zeolite-immobilized biomass also can be applied in the removal of nonmetals such as phosphorus and ammonium from aqueous solutions. Various factors are interfering in the cell immobilization and adsorption capacity such as carrier particle size, surface charge, and surface modification [51, 77, 79, 80]. Hrenovic et al.
2009 found that the number of immobilized cells correlated negatively with the size of support [77]. Also, Mery et al. 2012 studied the effect of zeolite particle size (0.5, 1.0 and 2.0 mm) on adherence of microorganism and adsorption capacity of ammonium, and their results showed that the greatest amount of zeolite adhered biomass was achieved for a particle size of 1 mm whereas the highest adsorption capacity of ammonium was obtained in a size of 0.5 mm [51]. As it mentioned, other factors influencing the adsorption of the microorganism in immobilization and adsorption capacity are the surface charge (defined by zeta potential) of both support and microorganism [77] and surface modification [80]. Hrenovic et al. 2009 reported that the increase of the zeta potential of supports correlated negatively with the number of immobilized cells [77]. Also, surfactant-modified zeolites (SMZ) were used as a support for Orthophosphate (p)-accumulating bacteria to remove phosphorus from wastewater. According to the results, zeolite surface modification concluded in the change of the zeta potential of particles (from negative to positive) and improvement in adsorption capacity [80].

4. Algal Immobilization

4.1. Algae. One of the most famous photosynthetic organisms that are capable of living and growing in many different environmental conditions is algae [81]. Instead of using bacteria to treat wastewater, it is also possible to use algae due to the existing nutrient sources present in wastewater such as nitrates and phosphates. Algae can uptake those nutrients and use them for their cell growth [82]. Most of the researchers in the area of biotechnology prefer to work on algae because of their advantages such as producing biomass without needing many resources, increasing the level of oxygen in water effluents, reducing the level of carbon dioxide, and reaching lower operational costs [3]. Based on morphology and size, algae are classified into two groups: macro and micro. Macroalgae (or seaweed) are composed of multiple cells and divided into three groups of brown, green, and red based on their pigmentation. Microalgae are unicellular and classified into three most important groups: diatoms, green, and golden [83]. Algal biomass can be used in various applications, including production of primary and secondary metabolites for food, cosmetic and pharmaceutical industries [3, 14, 58, 84], biofuel and bioenergy [3, 14, 84–87], wastewater treatment process [3, 14, 82, 84, 88–101], animal feedstock enhancer [81], and agriculture purposes [3, 14, 94]. One of the significant applications of algae is in the bioremediation area. Various species of microalgae, including eukaryotic and prokaryotic and also their inactive forms, can be used for the bioremediation of metal ions [99]. They can be considered as suitable biosorbents due to some characteristics such as their abundance in seawater and fresh water, high metal sorption capacities, reusability, and cost-effectiveness [96]. Microalgae have been reported to have higher metal ions biosorption capacity than other microorganisms like fungi, cyanobacteria, and bacteria [3, 102, 103]. This is due to the fact that the algal cell wall has a number of functional groups such as amino (—NH$_2$), hydroxyl (—OH), carboxyl (—COOH), phosphoryl (—PO$_3$O$_2$), sulphydryl (—SH), etc. that are mostly responsible for metal ions biosorption [82, 88, 95, 98]. As shown in Figure 2, the process of metal uptake by microalgae can be explained in two ways: the first step is rapid adsorption onto the surface of the cell, and the second step is via the absorption or intracellular uptake that is dependent on cell metabolism [82, 95]. The process of metal ion adsorption includes their binding on the cell wall, cytoplasmic membrane, capsule substances, and extracellular compounds (external polysaccharides) [13, 95] whereas the process of metal ion adsorption includes binding to phytochelatins, metallothioneins, cytoplasmic ligands, etc. [95].
4.2. Immobilization of Algal Biomass and Its Applications. Harvesting algal biomass from water streams, either culture medium or treated wastewater, is one of the most important challenges especially in a large-scale application. Harvesting methods such as mechanical, electrical, chemical, and biological techniques are not preferable due to the high assumption of chemicals and energy [100]. Immobilization of algae can be an alternative method to overcome the issues [100]. The immobilization of algae has been started over 40 years ago [4, 59]. The advantages of immobilization are shown in Table 1. The algal immobilization can provide high-value algal biomass [3, 14] which is different than the suspended one in the content and composition of lipid/chlorophyll, cell size, surface charge, protein content, and molecular compositions [104]. Zeng et al. 2013 studied the Chlorella sp. immobilization within a polymeric carrier and found that the immobilized cells achieved a total lipid and chlorophyll content of 14.85% and 3.36%, respectively, which was higher than suspended ones [104]. In addition, Zeng et al. 2013 reported that although the microalgal cell growth in immobilized cultivation was slower than the suspended cells (due to their mass transfer problems), the capsule-immobilized microalgae had a systematic growth of the algal cells [105]. The similar finding was achieved by Mallick et al. 1994 who worked on the immobilization of Anabaena dolio and Chlorella vulgaris and their results revealed that the agar-immobilized algae had a slow growth rate [106]. Furthermore, algal immobilization can increase the biosorption capacity and biomass activity as well [3]. The ability of microalgae in the attachment process depends on various factors, which are the age of microalgae whether it is in the exponential growth phase or in the stationary phase, culture state, and composition of the culture medium [13]. Furthermore, other important factors that influence the algal immobilization are the cell wall composition and surface charge of cells and carrier [107]. Eroğlu et al. 2012 used chitosan nanofiber mats for the immobilization of Chlorella vulgaris. They reported that microalgae cell walls consisted of various polysaccharides compatible with the support surface and also Chlorella cells surface has a negative surface charge (related to uronic acid and/or sulfate groups) that makes an electrostatic attraction to chitosan with the positive charge (resulting from primary amine groups) [107]. In the case of immobilization support, natural biopolymers and synthetic compounds (e.g., alginate, carrageenan, agar, polyacrylamide, polypropylene, and silica gel) have been used for the algal immobilization [13, 17, 95]. Researchers often prefer to use natural polymers due to their low toxicity [17]. Among natural polymers, alginate [3, 13, 17, 102, 108] and carrageenan [3, 13] have been widely used for the algal immobilization. On the other hand, polyacrylamide [17, 109, 110] has been extensively used as a synthetic polymer due to the fact that it is more resistant than the natural polymers [17]. Also, some researchers have used other supports such as loofa sponge, chitosan, and polymer carriers [104, 106, 107, 111]. Akhtar et al. 2004 found that loofa sponge was an effective support for the entrapment of microalgae [111]. Also, Mallick et al. 1994 reported that the immobilization on chitosan was more efficient than other beads like agar, alginate, and carrageenan [106]. In addition, Eroğlu et al. 2012 reported that chitosan nanofiber mat can be used as a water-insoluble and nontoxic support for algae [107]. Zeng et al. 2013 used sodium cellulose sulphate/poly-dimethyl-diallyl-ammonium chloride (NaCS-PDMAAAC) capsule for the immobilization of Chlorella sp. and their results showed that the immobilized cells had a robust morphology [104]. Table 4 lists various supports for algal immobilization. Immobilized microalgae can be harvested and converted to produce a variety of applications, including biofuel [3, 13, 58], removal of BOD, COD [112, 113], metal ions [14, 95, 102, 106, 108, 109, 111, 113–124], nonmetals [3, 11, 14, 106, 107, 112, 113, 119, 125–131], and use as a biosensor to measure the degree of water pollution [13, 14], toxicity of substances, and effluents in electronic devices [58] and as photosynthetic solar cells [132]. Table 4 summarizes the related researches on algal immobilization.

4.2.1. Production of High-Value Metabolites. Immobilized algae can be applied to the production of valuable metabolites. Desmet et al. 2015 synthesized a robust (Ca-alginate-SiO$_3$)-polycation) shell: (Na-alginate-SiO$_3$)$_2$ core hybrid system for use in an encapsulation of Dunaliella tertiolecta. They reported that high photosynthetic activity was achieved over a long time (more than one year). The system can be applied in harvesting high-value compounds, producing biofuel cells to photosynthetic solar cells for production of electricity, energy transformation, etc. [132].

4.2.2. Removal of Nitrate and Phosphate. Nutrient removal, including nitrate and phosphate, is another application of immobilized algae [11, 107]. Eroğlu et al. 2012 used chitosan nanofiber mats immobilized Chlorella vulgaris to remove nitrate from liquid effluents. They reported that around 30% of initial nitrate value was diminished within the first two days by chitosan uptake (physicochemical adsorption) and, after that, the remaining nitrate uptake continued with the growth of algae using it for its cellular metabolism. Their results also showed the overall removal rate of 32 ± 3% for Chlorella-absent and 87 ± 4% for Chlorella-attached chitosan mats [107]. Zeng et al. 2012 used Chlorella sp. and entrapped the cells in a polymer carrier of sodium cellulose sulphate/poly-dimethyl-diallyl-ammonium chloride (NaCS-PDMAAAC) to make algal capsules for the removal of total nitrogen (T-N) and phosphate (PO$_4^{3-}$-P) from artificial wastewater. Their results showed that high removal rate of 12.56 mg/g biomass per day for T-N and 10.24 mg/g biomass per day for PO$_4^{3-}$-P was achieved at the end of the treatment process [11].

4.2.3. Removal of Metal Ions. The amount of metal ion uptake in suspended and immobilized algal systems is different. On the one hand, the biosorption capacity of immobilized systems is higher than the suspended one and on the other hand, the number of repetitions in immobilized cells makes the researchers shift from the suspended to the immobilized one in the removal of metal ions [11, 117, 124]. Nasreen et al. 2008 used Chlorella sorokiniana for immobilization in loofa sponge as a biosorbent for the removal of Cr(III)
Table 4: Various types of immobilized microalgae and their applications.

| Microalgae strain | Kind of support          | Applications                  | Findings                                                                 | References |
|-------------------|--------------------------|-------------------------------|--------------------------------------------------------------------------|------------|
| *Chlorella vulgaris* | Chitosan nanofiber mats  | Nitrate removal               | Around 87% removal                                                       | [107]      |
| *Chlorella sp.*    | Sodium alginate beads    | Copper and zinc removal       | Biosorption capacity of 33.4 for copper and 28.5 mg/g for zinc           | [123]      |
| *Chlorella sp.*    | NaCS-PDMAAAC             | Total nitrogen (T-N) and phosphate (PO$_4^{3-}$-P) | Removal rate of 12.56 for T-N and 10.24 mg/g biomass per day for PO$_4^{3-}$-P | [11]       |
| *Scenedesmus quadricauda* | Ca-alginate beads | Removal of Cu(II), Zn(II) and Ni(II) | Maximum adsorption capacity of 75.6, 55.2 and 50.4 mg/g for Cu(II), Zn(II) and Ni(II) | [108] |
| *Scenedesmus sp.*  | Chitosan                 | Removal of nitrate and phosphate | 70% nitrate and 94% phosphate removal                                    | [131]      |
| *Chlorella sorokiniana* | Loofa sponge        | Removal of Cr(III)           | Maximum biosorption capacity of 69.26 mg Cr(III)/g biosorbent           | [124]      |
| *Chlorella vulgaris* and *Scenedesmus rubescens* | The twin-layer system | Removal of nitrogen and phosphorus | Removal to less than 10% of the initial concentration | [125] |
| *Tetraselmis chui*  | Calcium alginate         | Removal of Cu and Cd         | Removal of all Cu and removal of around 20% of total Cd                 | [115]      |
| *Scenedesmus intermedius* and *Chlorella and Nannochloris sp.* | Calcium alginate beads | Phosphorus (P) and nitrogen (N) uptake | 0.012 mg P h$^{-1}$ and 0.009 mg N h$^{-1}$ for Scenedesmus intermedius and 0.009 mg P h$^{-1}$ and 0.006 mg N h$^{-1}$ for Nannochloris sp. | [127] |
| *Chlorella sorokiniana* | Loofa sponge           | The removal of nickel(II)    | Biosorption capacity of 60.38 mg nickel(II)/g                           | [111]      |
| *Trentepohlia aurea* | Filter paper            | Removal of inorganic nitrogen sources | The removal rate of total inorganic N ion of 5.11 mg N l$^{-1}$ day$^{-1}$ | [128] |
| *Chlorella sorokiniana* | Vegetable sponge of Luffa cylindrica | Cadmium removal              | The cadmium sorption capacity of 192 mg/g                               | [116]      |
| *Chlorella sorokiniana* | Luffa sponge discs      | Removal of Ni(II)            | The removal of 97% of equilibrium loading                               | [117]      |
| *Chlorella vulgaris* | Calcium alginate beads  | Removal of N and P           | 100% removal of NH$_4^+$-N and around 95% reduction of PO$_4^{3-}$-P   | [129]      |
| *Chlorella homosphaera* | Sodium alginate         | Biosorption of cadmium, zinc and gold | Near 100% metal removal for cadmium and zinc and 90% removal of gold | [121]      |
5. The Potential Application of Zeolite as an Ideal Carrier for Algal Immobilization

One of the most significant drawbacks in algal immobilization is finding a suitable carrier. Natural carriers such as carrageenan and alginate have the problem of low stability [13] and synthetic polymers such as polyacrylamide face the drawbacks of high cost and toxicity to living cells [17]. Although the researchers have tried many materials as a support such as loofa sponge, chitosan, and polymer carriers [104, 106, 107, 111], many works need to be done to prove its feasibility. The ideal carrier for the algal immobilization must fulfill some requirements such as nontoxicity, cheapness, acceptable process efficiency, being potential to reuse, and stability. However, it seems that reaching these aims and finding an excellent carrier with these characteristics need further researches and remain a challenge. One of the materials as a suitable candidate for algal immobilization is zeolite. As mentioned in this paper, to date, various types of zeolite have been successfully used for the immobilization of bacteria and yeast. If there is any possibility to apply them as a carrier for the immobilization of different types of algae, it needs to be researched. In case of successful immobilization, one of the most important applications of the bioparticle (i.e., zeolite-immobilized algae) can be in the biosorption process of metal ions in which zeolite acts as a carrier and probably contributes to the sorption process resulting in improved efficiency. All these possibilities need to be studied and justified in the future.

Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this paper.

Acknowledgments

The authors would like to appreciate the Department of Chemical and Environmental Engineering of Universiti Putra Malaysia (UPM) for providing suitable research facilities.
