**ABSTRACT**

**Objectives:** This study set out to pursue means of reducing mismatch in schoolboy rugby players. The primary objective was to determine whether application of previously reported thresholds of height and grip strength could be used to distinguish those 15-year-old boys appropriate to play under-18 school rugby from their peers. A secondary objective was to obtain normative data for height, weight and grip strength and to assess the variation within that data of current schoolboy rugby players.

**Design:** Cross-sectional cohort study.

**Setting:** 3 Scottish schools and ‘Regional Assessment Centres’ organised by the Scottish Rugby Union.

**Participants:** 472 rugby playing youths aged 15 years (Regional Assessment Centres) and 382 schoolboys aged between 12 and 18 years (three schools).

**Outcome measures:** Height, weight and grip strength.

**Results:** 97% of 15-year-olds achieved the height and grip strength thresholds based on previous reported values. Larger mean values and wide variation of height, weight and grip strength were recorded in the schoolboy cohort. However, using the mean values of the cohort of 17-year-olds as a new threshold, only 7.7% of 15-year-olds would pass these thresholds.

**Conclusions:** Large morphological variation was observed in schoolboy rugby players of the same age. Physical maturity tests described in earlier literature as pre-participation screening for contact sports were not applicable to current day 15-year-old rugby players. New criteria were measured and found to be better at identifying those 15-year-old players who had sufficient physical development to play senior school rugby.

**INTRODUCTION**

Since the advent of professionalism in 1995, injury rates in Rugby Union have increased in the adult game, and although unproven, the same is suspected in schoolboy rugby. Serious neck and spinal injuries are thought to be rare in youth rugby. In 2010, however, Allan reported an unprecedented increase in the incidence of catastrophic spinal injuries among teenage rugby players admitted to the Queen Elizabeth National Spinal Injuries Unit in Glasgow, disproportionate to the school-age playing population when compared with data for the other home nations. Physical mismatch between players was highlighted as a possible contributory factor in these injuries.

The avoidance of mismatch is traditionally addressed by playing schoolboys in their year groups; however, year groups combine at 16 to compete in senior (under-18) school rugby. In contrast to the other home nations, Scottish schoolboys aged 15 years are
Can maturity testing reduce mismatch in schoolboy rugby players?

regularly involved in senior school rugby, in part due to
the relatively small playing population and also due to
the tradition of leaving senior school at an earlier age.

It is well recognised that within any selected year group, a wide spectrum of physical maturity exists, and there is evidence that this is at its maximum between the ages of 13 and 15 years, during which peak growth velocity usually occurs. In some American states, a maturity assessment is used as pre-participation screening for some collision sports, and there is some evidence to suggest that matching athletes for physical maturity is associated with a reduced injury rate. Previous studies have correlated specified height and grip strength values with the attainment of physical maturity as defined by the Tanner scale. A similar maturity assessment was introduced by the Scottish Rugby Union (SRU) in the hope that, by differentiating 15-year-old players by physical maturity, the risk of mismatch in this age group may be reduced.

The aim of this study was to determine whether the application of previously reported threshold measurements of height and grip strength could be used to distinguish those 15-year-olds who might safely play senior (under-18) school rugby. A secondary objective was to obtain normative data for physical characteristics (height, weight and grip strength) and to assess the variation within that data of current day schoolboy rugby players to investigate whether it might give a more sensitive assessment of physical maturity.

MATERIALS AND METHODS

At the beginning of the 2009–2010 season, the SRU ruled that no 15-year old should play in the front row in senior school rugby. Any 15-year old wishing to play senior school rugby in an alternative position was required to undergo a maturity assessment (based on previously reported values). This was introduced as part of an intervention to improve safety in the game (‘Are you ready to play rugby?’) and had been recommended by a subgroup of the Scottish Committee for Orthopaedics and Trauma in response to the increasing number of serious neck injuries observed in schoolboy rugby in Scotland.

An initial cohort of boys aged 15 years who wished to play senior school rugby was assessed by trained medical personnel, at several SRU-organised Regional Assessment Centres across Scotland. A specific testing protocol was followed for grip strength, height and weight. Grip strength was assessed with hand-held dynamometers (Jamar, Asimow Engineering Co, Los Angeles, California, USA), calibrated as per the manufacturer’s recommendations. Testing was undertaken as recommended by the American Association of Hand Surgeons with the subjects seated, the elbow flexed at 90° and the wrist in neutral. After an initial trial, three attempts were made and the mean calculated. Standardised verbal encouragement was given during the test; the boys were blinded to the values achieved until the test had been completed. Both hands were tested and the greater mean value used for analysis. Height and weight were measured using a Leicester Height Measure and Seca 761 Approved Medical Mechanical Floor Scales (Class III), respectively. To be regarded as physically mature, and therefore able to play in the under-18 age group, players had to fulfil the following physical conditions: height >165 cm and grip strength >25 kg.

In the second part of this study, a cohort of 382 rugby playing boys aged 12–18 years were assessed at three Scottish rugby playing secondary schools between December 2009 and October 2010. Height, weight and grip strength were measured by trained personnel using the same standardised protocol and equipment as in the initial cohort. Ethical approval was obtained from the Fife and Forth Valley Ethics Committee (REC No: 09/S501/62) to undertake this part of the study. Individual consent was obtained from the boys who participated and countersigned by their parents where appropriate. Supervision of the study was by members of the Scottish Committee for Orthopaedics and Trauma subgroup.

Data analysis

Data were analysed using SPSS (V.14, IBM). Data were manually assessed for normality with histograms. Descriptive data are reported as means with SDs as a measure of dispersion. Differences between age grades were assessed with one-way analysis of variance (ANOVA, General Linear Model). A Bonferroni correction was applied to reduce the chance of a type 1 error associated with multiple testing. Effect sizes are reported with the Eta² statistic. Post hoc tests were performed with Tukey’s HSD test to assess individual comparisons. Statistical significance was accepted as p<0.05.

RESULTS

Four hundred and seventy-two boys aged 15 years presented to the SRU-arranged Regional Assessment Centres. Their mean height was 177 cm (SD 7 cm, range 156–199 cm), mean weight 74.4 kg (SD 13.1 kg, range 46.0–127.1 kg) and mean grip strength 44.2 kg (SD 7.7 kg, range 20.5–80.0 kg). Using the criteria established from previous studies as an indication of physical maturity (height >165 cm, grip strength >25 kg), 97.2% were deemed physically mature and thus eligible to play in the under-18 age group.

Three hundred and eighty-two schoolboy rugby players aged 12–18 years were similarly assessed in the second cohort study at the three schools. Mean height, weight and grip strength generally increased with age, reflecting growth (table 1 and figure 1).

Variation in all physical parameters (height, weight and grip strength) was determined by age group (ANOVA). Modest to large effect sizes were observed for each parameter (table 2).

Post hoc testing (Tukey’s HSD test) demonstrated significant differences between each variable in every age group up to the age of 15 years. No significant differences
were observed between the 16, 17 and 18 years age groups for height or grip strength nor between the 15, 16, 17 and 18 years age brackets for weight (table 3).

Differences were, however, apparent between the 15 and 17 years age groups for height (difference in mean =4.80, 95% CI 0.97 to 8.65), weight (difference in mean =8.53, 95% CI 2.73 to 14.34) and grip strength (difference in mean =5.41, 95% CI 1.79 to 9.03).

As the median age of boys playing senior school rugby in Scotland was 17 years, we assessed how many 15-year-olds would meet the mean height, weight and grip strength of the 17-year age group: 180 cm height, 76 kg weight and 43 kg grip strength. The numbers meeting each of these criteria, and various combinations of the criteria, are shown in table 4. Only 13.8% of the 15-year-olds had the mean grip strength and height of a 17-year old, while including weight as an additional requirement reduced this figure to 6.2%.

The effect of applying thresholds to the cohort data is highlighted in figure 1, where the heavy dashed line

**Table 1** Physical parameters by age grade, mean (SD)

| Age (years) | 12  | 13  | 14  | 15  | 16  | 17  | 18  |
|-------------|-----|-----|-----|-----|-----|-----|-----|
| Participants (n) | 54  | 66  | 63  | 65  | 55  | 62  | 17  |
| Height (cm) | 155 (7.6) | 163 (7.8) | 170 (7.5) | 175 (7.0) | 179 (7.5) | 180 (6.2) | 182 (8.1) |
| Weight (kg) | 48 (9.2) | 54 (10.8) | 61 (9.8) | 68 (11.4) | 72 (10.2) | 76 (12.8) | 84 (14.9) |
| Grip strength (kg) | 23 (3.9) | 27 (5.0) | 33 (8.1) | 38 (6.9) | 42 (8.1) | 43 (8.1) | 46 (6.9) |

**Figure 1** Assessed physical parameters with cut-off thresholds. Mean values with 95% CIs for (A) height, (B) weight and (C) grip strength of the 382 schoolboys assessed. The heavy dashed line represents the 17-year-old mean and allows direct comparison of the number of younger boys likely to achieve this value. The lighter dashed line reflects the previously used criteria (height and grip strength only) demonstrating the poor reflection of these previous scores on current day Scottish schoolboy rugby players.
The professional game has become more physical, and injuries in elite players are commonplace. The popularity of rugby as a sport for teenagers is reattened by concerns about the potential for serious injury. The historical grip strength requirement, and 13-year-olds (95% CI of mean) meet the historical height requirement, are significant across age groups in the schoolboy study (ANOVA, table 2), post hoc testing reveals initial year on year significant differences only up until the age of 15 years. Thereafter, the trend of increasing mean values continues in weight and grip strength, but mean height increases are seen to level off over 16 years (figure 1).

Height was previously recognised as an important determinant of physical maturity with the period of peak growth around the ‘growth spurt’ associated with an increased risk of injury. Peak height velocity occurs at a median age of 14 years in North American boys, with the 95% CI extending from 11.5 to 15.5 years. It is then not surprising that height is less likely to be a discriminator when the 13-year age group, at the upper limit of the growth spurt, is being assessed. From the normative data obtained, it seemed more logical to compare the height, weight and grip strength of 15-year-olds with the means of those age groups they would encounter if they played in senior school rugby. As 17 years is the median age of senior school rugby (16–18-year group), the

| Table 2 | Effect of age on variance in assessed physical parameters (analysis of variance) |
|---------|---------------------------------------------------------------------------------|
|         | F (6, 382) | Significance, p value | $$\eta^2$$ |

| 15–16 | 4.22 (0.26 to 8.19) | 0.028 | 4.45 (−1.52 to 10.42) | 0.292 | 3.82 (0.08 to 7.56) | 0.042 |
| 16–17 | 0.58 (−3.43 to 4.59) | 0.1 | 4.08 (−1.97 to 10.14) | 0.417 | 1.59 (−2.19 to 5.37) | 0.876 |
| 17–18 | 1.94 (−4.13 to 8.01) | 0.964 | 7.90 (−1.26 to 17.05) | 0.142 | 2.84 (−2.88 to 8.56) | 0.763 |
mean values for a 17-year old were chosen as threshold values, which a 15-year old should achieve if he were to enjoy a degree of physical compatibility with these older players, hopefully reducing his risk of injury. Table 4 highlights the effect of applying the mean values of the 17-year-old boys to the 15-year-old age group. When the different combinations of height, weight and grip strength were assessed, height proved to be the least discriminatory, as predicted. It has been recorded that there is a group of taller boys who, while regarded as pubertally mature, do not possess the muscular strength of peers of similar height.\textsuperscript{15} It was therefore decided that grip strength and weight should be selected as the key parameters for testing. Using these parameters alone, 7.7\% of 15-year-olds in this cohort achieved the mean weight and grip strength of a 17-year old.

While mismatch is recognised as an issue internationally, neither maturity nor grip strength testing is routinely tested in the major rugby playing countries. In New Zealand, both age and weight are taken into account in banding for youth rugby. Players who are significantly heavier than their peers may play at a more senior grade and underweight individuals may play down an age grade, although variation does exist between different districts. South African youth rugby is banded according to age, with players only able to play within a certain age group if their age falls within 2 years of that group. The BokSmart\textsuperscript{23} rugby safety initiative was launched by the South African Rugby Union in 2009 to combat a comparatively high rate of catastrophic injuries, both in youth rugby and in senior rugby. This was a similar programme to the RugbySmart initiative in New Zealand,\textsuperscript{24} which commenced in 2001 and has been shown to reduce the incidence of spinal injuries.\textsuperscript{25} BokSmart includes comparison of individuals with normative data for age groups, including body mass, fitness tests and some basic strength tests. Guidelines for players wishing to play out with their age group are well defined, requiring full rugby-specific assessments by qualified sports practitioners, letters from conditioning coaches, team doctors and coaches, confirming the suitability of the player. A similar approach exists in Australia with streaming according to age group up to U19 level, and players being unable to compete more than 2 years above their respective age group.\textsuperscript{26} Those who wish to play up beyond the 2-year window require their coach to fill out an exemption form addressing issues, such as level of experience, playing position, use of strength training, and perceived level of maturity. In none of these countries do any objective criteria exist for physical testing.

Currently, the SRU have adopted the condition that any 15-year old wishing to play under-18 rugby, in a position other than the front row, has to achieve the mean weight and grip strength of 17-year-old players. Front row players aged 15 years are not allowed to play in the under-18 age group; this decision was based on reports in the literature that serious neurological damage was more common following neck injury sustained in the scrum in UK schoolboys rather than the tackle.\textsuperscript{7} Specified under-16 age group rugby exists in some countries, and the delay this imparts on the progress of 15-year-olds into senior school rugby is logical, particularly as this may coincide with a time in their physical development where there is greatest variation in physical maturity. To date, our focus has been on the 15-year age group. With further data collection, it may be that criteria could be identified for all age bands, with players of similar physical development playing together as they mature at differing rates. Potentially, this could identify more developed individuals who should play in older age groups, thus reducing the risk of injury to their age peers or immature individuals who should play in younger age groups, reducing their own risk of injury.

In the absence of robust injury data, but confronted with an upsurge in serious neck injury in Scotland, it was felt that the introduction of maturity assessment in schoolboy rugby was a valuable adjunct to other measures that have been taken to increase safety. To date since the inception of these measures, no schoolboy rugby player with a serious neck injury has been admitted to the National Spinal Injuries Unit in Glasgow. It is accepted, however, that the screening method we are proposing is hypothetical without any injury data to support its efficacy. It is, however, based on current population data involving schoolboy rugby players, applying concepts established in American schools contact sports, based on the only literature available on this subject.

In conclusion, we have demonstrated that maturity testing using previously reported parameters fails to differentiate between current day 15-year old Scottish schoolboy rugby players. Matching schoolboys for weight and grip strength, introducing a safety margin based on current population data, where younger players wish to
Can maturity testing reduce mismatch in schoolboy rugby players?

Compete above their age group is more likely to be an effective method of reducing mismatch.

Reducing the risk of injury in contact sports should be a universal aim, and it will only be achieved once we know accurately the size and severity of the problem. Previous authors have expressed concerns regarding the wide variation in shape and size of same-aged schoolboys. We suggest that inclusion of indicators of physical maturity within an injury surveillance framework is important if we are to establish the risks associated with mismatch of age grade players. Until such data are available, it would seem logical to try and minimise mismatch, which is what we have set out to achieve with this initiative.

Acknowledgements The authors acknowledge the assistance of the staff at the three secondary schools visited, particularly the heads of department for physical education. Thanks must also be paid to the continued support from the Scottish Rugby Union, and in particular to the efforts of Nick Rennie and Dr James Robson. The authors also thank the doctors, physiotherapists, medical students and research personnel for the organisation of testing and gathering of the data. Special thanks must go to Deborah MacDonald, Gavin MacPherson, Sally-Anne Phillips and Robert Wallace.

Contributors RWN, DFH, JDH, HS and JGBM were involved in the conception and study design. All authors were involved in data collection. DFH performed the analysis, MJM drafted the initial manuscript. All authors contributed to the revision of the draft manuscript and approved for submission.

Funding The first cohort of testing was funded by the Scottish Rugby Union. The second cohort of schools-based testing received support from the Hearts and Balls charity to purchase testing equipment.

Competing interests None.

Ethics approval Ethics approval was provided by the Fife and Forth Valley Ethics approval (REC No 09/S501/62).

Provenance and peer review Not commissioned; externally peer reviewed.

Data sharing statement The data are held in a secure database at the University of Edinburgh, any party wishing to access unpublished data should discuss with the corresponding author.
