Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Parents under stress: Evaluating emergency childcare policies during the first COVID-19 lockdown in Germany

\begin{abstract}
What are the effects of school and daycare facility closures during the COVID-19 pandemic on parental well-being and parenting behavior? Can emergency childcare policies during a pandemic mitigate increases in parental stress and negative parenting behavior? To answer these questions, this study leverages cross-state variation in emergency childcare eligibility rules during the first COVID-19 lockdown in Germany and draws on unique data from the 2019 and 2020 waves of the German AID:A family panel. Employing a triple-differences approach we identify short- to medium-term intention-to-treat effects and find that while emergency care policies did not considerably affect parents' life satisfaction, partnership satisfaction or mental health, they have been effective in diminishing harsh parenting behavior. We find partly gendered effects, specifically on paternal parenting behavior. Our results suggest that decreasing parental well-being likely constitutes a general effect of the pandemic, whereas the observed increase in negative and potentially harmful parenting behavior is largely directly caused by school and daycare facility closures.
\end{abstract}

1. Introduction

Confronted with nationwide closures of schools and daycare facilities due to the COVID-19 pandemic in spring 2020, many parents in Germany suddenly had to overhaul their work-care-arrangements. Only a very limited number of parents who between them had a specific constellation of systemically relevant occupations were granted access to emergency childcare (henceforth referred to as EC). In this paper, we exploit plausibly exogenous variation in eligibility rules across German federal states to evaluate the effect of emergency childcare policies on parental well-being and parenting behavior during the pandemic. Closed schools and childcare facilities, work from home arrangements, social distancing policies, and financial and health-related worries during the first lockdown created a stressful environment for families. These circumstances are likely to increase parenting stress, which in turn, might negatively influence parenting behavior (Abidin, 1992; Jackson and Choi, 2018). Previous research indicates a positive association between negative parenting behavior and higher levels of children externalizing and internalizing problems, even if negative parenting behavior occurs infrequently (Pinquart, 2017). Moreover, harsh parenting has also been shown to be a risk factor for child abuse and neglect (Lee, Grogan-Kaylor, and Berger, 2014).

We employ a difference-in-difference-in-differences (DDD, or: triple differences) design to identify intention-to-treat (ITT) effects. We leverage cross-state variation in EC eligibility rules during the first COVID-19 lockdown in Germany, and can hence compare outcome changes of systemically relevant parents with EC access to outcome changes of equally systemically relevant parents in other states without EC access. This controls for the fact that systemically relevant parents (nurses, doctors and other key workers) are specifically affected in pandemic times, irrespective of EC. This cross-state comparison is based on the assumption that, were it not for EC policies, outcome changes for systemically relevant parents would have been similar across federal states. However, federal states were differently affected by the pandemic and hence reacted differently. To control for state-specific shocks that may have affected parents, we hence additionally use outcome changes for parents with no systemically relevant occupation between them, resulting in a triple-difference design. The ITT parameter resulting from the triple-
difference design, i.e. the causal effect of emergency childcare eligibility, is the most policy relevant parameter since eligibility is the lever that policy makers primarily control. However, since substantive two-sided non-compliance in the context of pandemic emergency childcare (due to self-protective parental behavior and fuzzy implementation of the eligibility rules) is to be expected, we provide supplementary IV-LATE analyses to rescale ITT effects and to characterize compliers. The LATE parameter represents the causal effect of emergency childcare utilization.

We draw on unique data from two waves of a German family panel “Growing up in Germany: Everyday Worlds” (AID:A) that surveyed families in 2019 and 4 to 5 months after the first COVID-19 lockdown in 2020. Based on a sample of 646 parents, we find that EC was not able to permanently shelter families from a considerable reduction in parental well-being. However, the provision of EC was effective in diminishing increases in harsh parenting in terms of ‘becoming angry’ among the EC-eligible parents. This effect of EC is evident several months post-lockdown, more pronounced in families with children of preschool-age or younger, and completely cancels out increases in harsh parenting among compliers. Furthermore, for fathers only, we find that EC prevented decreases in positive parenting behavior (child-centered communication), and increases in harsh parenting in terms of ‘punishing harder than merited’. Evaluating short- to medium-term effects, we likely measure lower bounds of immediate effects during the lockdown and identify the persistent component of the overall impact.

Our results disentangle effects caused directly by school and daycare closures from general effects of the pandemic since by studying families that use childcare, we are able to compare families that experienced a complete disruption of external childcare provision with those that, thanks to their access to EC, did not. This comparison is most meaningful for children in daycare where EC was quantitatively and qualitatively more equivalent to the pre-pandemic situation than EC for school-children. We find that, while decreasing parental well-being appears to be a general pandemic effect rather than a specific effect of the closures, the observed increase in negative and potentially harmful parenting behavior is largely directly caused by school and daycare closures.

These findings contribute to the growing body of empirical literature on how the COVID-19 pandemic affects families and family well-being1. We add to the existing literature by providing a first rigorous evaluation of EC policies, evaluating short- to medium-term (by August, September 2020) rather than immediate effects, by exploiting intra-individual variation in a range of parental well-being and parenting behavior indicators. Furthermore our analysis relates to previous literature evaluating expansions in early childhood education and care (ECEC) on maternal labor market participation, parental well-being and child development (e.g. Bauernschuster and Schlötter, 2015; Schmitz, 2020; van Huizen and Plantenga, 2018). We contribute to this strand of literature by evaluating the effects of a temporary disruption in external childcare provision. In a similar vein, our analysis contributes to the economic literature evaluating consequences of schooling disruptions on educational attainment and later earnings (e.g. Belot and Webbink, 2010; Hansen, 2011; Jaume and Willén, 2019; Marcotte and Hemelt, 2008).

The paper is structured as follows: Section 2 describes the EC policies that were in place during the first COVID-19 lockdown in 2020 in the German federal states; Section 3 introduces the data used and describes sample selection; Section 4 presents the identification strategy; and Section 5 reports the main results, as well as compiler analysis and robustness checks. The final section concludes.

1 See e.g. Huebener et al. (2021) or Möhring et al. (2020) for empirical evidence on Germany and Prime, Wade, and Brown (2020) for a literature review on the possible consequences of the COVID-19 pandemic on well-being of families and children.

2 For six federal states, these data also include after-school childcare for school children.

3 To be eligible for EC, employers had to confirm systemic relevance.

2. Emergency childcare policies in the German federal states in 2020

In Germany, childcare options and their take-up depend heavily on the child’s age. Attendance rates are lowest for children under three. In 2019, only 34 percent of under-threes attended a childcare facility, with significant differences between East and West Germany, but also between urban and more rural regions. In contrast, daycare usage from the age of three is almost universal: daycare coverage for children aged three to five was over 90 percent in 2019 (BMFSFJ, 2020). Finally, by age six, 64 percent attend school, and reaching almost 100 percent by age seven (Statistisches Bundesamt, 2018).

During the nation-wide lockdown between mid-March and mid-April 2020, school and daycare closures were mandated in all German federal states. Moreover, to prevent the spread of COVID-19, and especially to protect the elderly, parents were encouraged not to rely on friends, neighbors, and grandparents for childcare support. Thus, many parents in Germany suddenly had to overhaul their work-care-arrangements and provide home-schooling on their own. However, a small number of parents with a specific constellation of systemically relevant occupations were granted access to EC. In the period between mid-March and mid-April 2020, all federal states provided “emergency childcare” based on parents’ occupational systemic relevance. Subsequently—according to a mutually agreed upon framework for the stepwise opening process (JFMK, 2020)—there was a phase of gradual re-opening where emergency childcare was steadily extended (“extended emergency childcare”). By June 2020, most federal states then switched to (restricted) normal operations of daycare facilities.

Fig. 1 depicts the utilized daycare capacity during the first COVID-19 lockdown and the subsequent re-opening phase based on data from the “Corona-Kita-Studie” (DJI and RKI, 2020), whereby weekly utilized daycare capacities represent the share of children that were in daycare compared to the total of children registered for daycare by March 2020. In the initial phase of the lockdown with EC—between mid-March and mid-April—on average 3 percent of the childcare capacities were utilized while subsequently, during the phase of extended EC, on average 27 percent were utilized.

EC was organized in a similar way for pre-school and school-age children. EC eligibility regulations were the same. No schooling was provided in EC for school-age children. (Lippert et al. (2020) report a 3 percent take-up rate of EC among elementary school children during the initial lockdown phase, which corresponds to the utilization rate of daycare among pre-schoolers.

In nearly all states (with exception of Hamburg and Saarland) parents’ occupational systemic relevance was a crucial factor for EC eligibility during the “emergency care” phase of facility closures. Systemically relevant occupations were defined as either occupations in the health and care sector (such as physicians, nursing staff or laboratory assistants) or occupations needed to maintain the infrastructure (such as in the energy or water industries, transportation, alimentation or public safety). Note that there is some variation, since German federal states applied stricter or looser definitions of systemically relevant occupations (Deutscher Bundestag, 2020; Blum and Dobrotić, 2021). Moreover, since in Germany, federal state and county-level authorities are responsible for education and social services, regulations regarding EC eligibility varied across federal states. Table 1 provides information about these differences in EC eligibility rules (see Fig. A.1 in the Appendix for a graphical display and Appendix Table A.1 for more detailed information). While in some states both parents had to work in a systemically relevant occupation to be eligible for EC (2-parent rule), in other states only one parent had to (1-parent rule). Additionally, in Bremen, Bavaria,
Saxony and Schleswig-Holstein, a “mixed rule” was applied according to which, to gain access to EC parents had to be either both in a systemically relevant occupation, or at least one parent had to work in an occupation in the health and care sector. In the federal states of Hamburg and Saarland, parents were encouraged to keep their children at home, but access to EC was not further regulated. Furthermore, while in some states the child’s age was also a limitation factor in whether it could be placed in EC, in others children’s grade determined the relevant upper limit.

Our analysis aims at identifying the impact of EC policies during the acute phase of school and daycare closures between mid-March and mid-April, exploiting the differences in eligibility rules across federal states as exogenous variation. Our empirical strategy abstracts from the effects of the subsequent provision of “extended emergency childcare” during the re-opening phase following the first COVID-19 lockdown, which is a key feature of our analysis. We feel it is important to focus on parents that had access to EC from the beginning of the lockdown, and hence experienced a significantly smaller disruption of daycare provision in comparison to all other parents that had children in daycare pre-pandemic (including those that utilized extended emergency childcare after two months of childcare at home). In view of the fact that in many cases emergency childcare did not provide full-time daycare, our estimates likely represent the lower bounds of the true effects.

3. Data and sample selection

Our analysis uses data from the 2019 wave of the AID:A family panel (Kuger et al., 2020), that surveyed about 6,000 households on living conditions of children, youth, young adults and parents. We combine this data with information from the “AID:A Corona Add-on” study (Kuger et al., 2021), which re-interviewed about 780 households in August and September 2020 on their current living conditions, as well as their circumstances during the first COVID-19 lockdown in Germany in March 2020 and subsequent re-opening.

Fig. 1. Utilized childcare capacity in Germany during the first COVID-19 lockdown in early 2020 and subsequent re-opening.

Note: Utilized daycare capacity represents the share of children that are currently in daycare among those children that were registered in daycare by March 2020. DJI-RKI (2020) reports these shares weekly by federal state, based on communications from the respective federal state ministries; we subsequently aggregate those shares to the national level. Not all federal states report utilized capacities every week (week of Mar 16: N=9, Mar 23-30: N=13, Apr 6-13: N=14, Apr 20-June 1: N=15, June 8-15: N=12, June 22: N=11, June 29: N=7). There is no information available on the federal state of Baden-Württemberg throughout. For six federal states, these data also include after-school childcare for school children.

We define the timing of transition from emergency childcare to extended emergency childcare and from extended emergency childcare to the phase of (restricted) normal operation as the week where more than five observed federal states switch status, based on information from DJI-RKI (2020, Table 1).

Source: DJI-RKI (2020); own calculations.

Table 1

| Systemic Relevance (SR) | Federal States |
|------------------------|----------------|
| Both parents SR | One parent SR health/care: yes | One parent SR health/care: no | No parent SR |
| All access | yes | yes | yes | HHL, SL |
| 1-parent rule | yes | yes | no | BE, HE, NI, RP |
| Mixed rule | yes | no | no | BY, HB, SN, SH |
| 2-parent rule | yes | no | no | BW, BB, MV, NW, ST, TH |

Note: “All access”: parents are encouraged to keep their children at home, but access to EC is not further regulated. “1-parent rule”: at least one parent has to work in a systemically relevant occupation to be EC eligible. “Mixed rule”: parents have to either work both in a systemically relevant occupation or at least one parent works in an occupation in the health and care sector to gain access to EC. “2-parent rule”: both parents have to work in a systemically relevant occupation to be eligible for EC. Lower Saxony and Schleswig-Holstein adjusted their regulations after the first week of lockdown. We employ the adjusted regulations. The eligibility rules summarized here concern the first phase of emergency childcare. Eligibility expanded in the subsequent phase of extended emergency childcare, whereby all federal states except Thuringia (where the 2-parent rule remained in place) applied the 1-parent rule. See also Table A.1 for a more detailed overview.

Depending on the federal state, during the extended EC period, EC eligibility was extended to single parents, parents of pre-school children, parents of children with special educational needs, or federal states widened their definition of occupational systemic relevance or switched from a “2-parent rule” to a less restrictive “1-parent rule”.
and April 2020. Importantly for the purpose of our study, parents of children of pre-school age or younger were asked about their utilization of emergency childcare during the lockdown. Moreover, parents were also asked about their occupational “systemic relevance” and, crucially for our identification strategy, the type of systemic relevance (health-related or not). That is, respondents were not directly asked about their occupational systemic relevance, but whether they “work in the health or care sector” and whether they “work in a sector that is prescribed systemic importance, such as, for example, energy and water supply, transportation, alimentation or public security”. If partner information on systemic relevance is missing, we impute it via the partner’s occupation stated in 2019, based on the classification of systemic relevance employed in Koebe et al. (2020), which links up with occupations at the 3-digit KlDf 2010 level. This information allows us to determine parents’ eligibility for EC according to the official rules of the respective federal states of residence (see Section 2 and Table 1), irrespective of their reported utilization of EC. Note that the information on parents’ occupational systemic relevance is crucial for our ability to identify effects of emergency childcare abstracting from effects of extended emergency childcare.

Note also, that our measure of EC utilization does not distinguish between utilization during the immediate “emergency childcare” phase or the subsequent phase of “extended emergency childcare”. Only by instrumenting EC utilization with EC eligibility, can we tease out the local average treatment effects of EC use during the “emergency childcare” phase. We assume implicitly in our analysis that compliers in the IV analysis identify EC-eligible parents that actually utilized emergency childcare in the acute lockdown and not only extended emergency childcare in the subsequent phase of re-opening.

Estimating intention-to-treat effects on parental well-being and parenting behavior, we consider 636 parents from 482 two-parent families with at least one child below the age of 12 that was either in school or in external daycare when the pandemic hit Germany (Sample A). This sample is restricted to parents for whom we have full information on the main outcomes, and families for whom we have either information on occupational systemic relevance or occupational classification for both parents. Additionally, 16 families from federal states without within-state variation of EC access (Hamburg and Saarland according to Table 1) have been excluded, since they do not contribute to our identifying variation.

To estimate local average treatment effects, we consider a subset of 319 parents from 227 families with at least one child of pre-school age or younger who was in external daycare pre-pandemic (Sample B). We focus only on this group since unfortunately information on EC utilization was not collected for school children and is hence not available for the full sample (Sample A). Table 2 reports summary statistics for both samples.

About 54 percent of parents in our sample have no systematically relevant occupation in the parental couple and are thus not eligible for EC. Conversely, roughly 46 percent of parents have a specific constellation of systemically relevant occupations between them. However, only 23.4 (24.1) percent of parents in Sample A (B) are eligible for EC, with their specific constellation of systemic relevance in the parental couple matching the EC eligibility rule applied in their federal state of residence. The EC utilization rate, at 26.3 percent in Sample B is significantly higher than the observed eligibility rate, since the information on utilization does not distinguish between utilization during the period of “emergency childcare” (mid-March to mid-April 2020) and utilization during the subsequent period of “extended emergency childcare” (mid-April to end-May 2020) during which utilization rates increased significantly (see Section 2, Figure 1).

The information displayed in Table 2 also shows that, on average, all employed measures of parental well-being and parenting behavior worsened from 2019 to 2020. Life satisfaction decreased by on average 0.22 (0.25) points, partnership satisfaction by 0.13 (0.08) points on a 6-point scale from 1 “not at all” to 6 “very satisfied” for Sample A (B). Observed decreases in the WHO-5 Well-Being Index amount to on average 0.33 points on a 100-point scale for Sample A, and 0.55 for Sample B. Harsh parenting behavior increased in its frequency on average by 0.38 (0.36) points on a 6-point scale with respect to ‘becoming angry’, and less strongly in terms of ‘punishing harder’ with an average increase of 0.02 (0.06) points for Sample A (B). All outcomes measures have been surveyed via Computer Assisted Self-Interviewing (CASI) in 2019 and via Computer Assisted Web-Interviewing (CAWI) in 2020, to take the sensitive nature of the questions into account and prevent social desirability bias. In the further analysis, all outcome measures are standardized to have a mean of zero and a standard deviation of one.

4. Empirical strategy

The source of exogenous variation underlying our identification strategy mainly comes from the cross-state variation in EC eligibility rules during the first COVID-19 lockdown in Germany. Our identification strategy compares groups of parents with the same constellations of occupational systemic relevance, which differ in their EC eligibility due to variations in EC eligibility rules across federal states. We define EC-eligible parents as the “treatment group”, and parents that are in some constellation of systemically relevant occupation but who are not eligible for EC as the “control group”. For a more robust analysis, we add parents without any systemic relevant occupation in the parental couple as a further control group. In short, we rely on a triple-difference identification strategy that is robust to the presence of unobserved additive effects specific to the group of parents characterized by their occupational systemic relevance and to state-specific shocks. First, we can contrast variation over time in outcomes between parents that share the

education and social work, housekeeping, and theology” as the most common occupational classifications.

Self-reported general (or global) life satisfaction is recorded based on a short scale (Niethe et al., 2020), a valid and widespread way to measure general life satisfaction in an efficient manner (e.g. Lucas and Donnellan, 2012).

Global partnership satisfaction is measured by the German single-item version (Sander and Böcker, 1993) of the Relationship Assessment Scale (RAS, Hendrick, 1988). Recent research supports the validity and reliability of this commonly used one-item version of the RAS (Fülöp et al., 2022).

The World Health Organisation Well-Being Index (WHO-5) is a widely used and internationally validated measure for assessing subjective psychological well-being (Topp et al., 2015) consisting of five positively phrased items (WHO 1998). The resulting index ranges from 0 to 100, with higher scores reflecting a higher level of psychological well-being.

Survey measures of harsh parenting behavior are based on Schumacher et al. (1999) and Jaurusch (2003), and are included in all AID:A studies since 2009. Jaurusch et al. (2009) and Walper and Grigic (2013) show the reliability and validity of this scale, and show associations between negative parenting behavior and children’s antisocial and overall problem behavior.

Results for non-standardized outcomes are presented in Schüller and Steinberg (2021).
same constellation of systemically relevant occupations but, due to a different state of residence, may be eligible for EC or not. Second, we also control for the common shocks experienced by parents residing in the same federal state by controlling for changes in outcomes experienced by parents residing in the state without any systemic relevant occupation. These contrasts lead to our difference-in-difference-in-differences design (Wooldridge, 2010, p.151). In addition, we complement this ITT analysis with results based on an instrumental variable strategy, where we exploit the variation induced in EC eligibility to estimate the causal effect of EC utilization on parental outcomes, net of parent-individual fixed effects.

4.1. Regression Model of Intention-to-Treat Effects

To estimate the intention-to-treat effects of EC, that is, the effects of EC eligibility on parental well-being and negative parenting behavior, we use the following model in a triple differences setup:

\[ y_{irt} = \gamma_r + \alpha_i + \theta_s + \beta \text{Eligibility}_{ps} + \epsilon_{irs}, \]

where \( y_{irt} \) is the outcome of interest (parental well-being or parenting behavior, respectively) observed for parent \( i \) of systemic relevance (SR) constellation group \( r \) resident in state \( s \) in period \( t \) (with \( t = [2019; 2020] \)). The three dimensions of state \( (s) \), time \( (t) \) and SR constellation group \( (r) \) allow us to control non-parametrically for state-specific shocks \( (\gamma_r) \), interactions of SR constellation group and time effects \( (\alpha_i) \), as well as state-specific effects of SR constellation groups \( (\theta_s) \) under the assumption that all these effects are additive.

\( \text{Eligibility}_{ps} \) is our treatment variable, and results from the entanglement of the four SR constellation groups \( (r) \), the three state-specific eligibility rule types \( (s) \), and a period effect \( (t) \). Specifically, the four relevant SR constellation groups are “no parent SR”, “one parent SR, not health-related”, “one parent SR, health-related” and “both parents SR” (see Table 1). In federal states with a “1-parent rule”, all constellations except “no parent SR” are EC eligible; in federal states that apply a “2-parent rule” only the constellation of “both parents SR” is EC eligible; in federal states with a mixed rule, the constellations of “both parents SR”, as well as the constellation “one parent SR, health related” are eligible for EC. Our coefficient of primary interest \( \beta \) is a difference-in-difference-in-differences type estimator. This parameter is identified through (1) cross-sectional variation across states with different EC eligibility rules (with EC-eligible parents as the treatment group and parents in similar SR constellations who are not EC-eligible due to different state rules as a control group), (2) temporal variation in parents’ average outcome levels between the survey waves 2019 and 2020 (with the untreated year 2019 as control), and (3) temporal variation within states (with parents without a systematically relevant occupation as the “within-state” control group).

Throughout the analysis, all standard errors are clustered at the household level and are robust to heteroscedasticity. We show results from individual fixed effects regressions that additionally control for unobserved time-invariant factors, and improve precision with respect to pooled OLS.\(^{14}\) Note that all within-individual time-invariant factors (including \( \theta_s \)) are controlled for by the individual fixed effects.

---

Table 2
Summary Statistics.

|                      | Sample A: Families with children below age 12 | Sample B: Families with children of preschool-age or younger |
|----------------------|---------------------------------------------|-----------------------------------------------------------|
| Life satisfaction 2019 | 5.074 (0.775)                               | 5.107 (0.778)                                             |
| Life satisfaction 2020 | 4.857 (0.949)                               | 4.859 (0.969)                                             |
| Partner satisfaction 2019 | 5.072 (1.004)                             | 5.103 (0.974)                                             |
| Partner satisfaction 2020 | 4.943 (1.075)                              | 5.028 (0.919)                                             |
| ‘Become Angry’ 2019      | 2.525 (0.941)                               | 2.586 (0.977)                                             |
| ‘Become Angry’ 2020      | 2.907 (0.942)                               | 2.947 (0.911)                                             |

Source: AID/A 2019, AID/A Corona Add-on 2020; own calculations.

Notes: “Life satisfaction”: “How satisfied are you with your life, all things considered?” (1 “not at all satisfied” to 6 “very satisfied”). ‘Partnership satisfaction: “Overall, how satisfied are you with your relationship?” (1 “not at all satisfied” to 6 “very satisfied”). The World Health Organization Well-Being Index (WHO-5) is a five-item measure of self-reported current mental well-being (WHO 1998). The resulting index ranges from 0 “absence of well-being” to 100 “maximal well-being” (see Topp et al., 2015). ‘Become Angry’: “How frequently does the following occur? I quickly become angry when my child(ren) don’t do as I say” (1 “never” to 6 “almost always”). ‘Punish Harder’: “How frequently does the following occur? I punish my child(ren) harder than what they merit.” (1 “never” to 6 “almost always”).
For completeness, we additionally report the difference-in-differences (or double difference) results from the subsample of parents with some kind of SR constellation. That is, for the double-difference setup, we exclude the data for parents without any occupational SR in the parental couple, and we estimate Eq. (2), in which states are again subscripted with s, SR constellation groups with r, and time period with t:

\[ y_{rst} = y_s + \alpha_t + \theta_r + \beta \text{Eligibility}_{rst} + \epsilon_{rst}. \]  

(2)

The double-difference estimator assumes that, were it not for differences in EC eligibility rules, outcome changes for parents of the same SR constellation group would have been similar across federal states. However, there might well be state-specific period effects in the context of the COVID-19 pandemic and associated state-level policy measures that may have affected parental stress irrespective of EC policies. A neat way to account for state-specific shocks is in fact to use other groups that are not directly affected by EC policies in either state (such as parents without any SR occupation in the parental couple) as an additional control group in a triple-difference setup, as outlined above. Outcome changes in this group, which is unaffected by the policy of interest, are then presumed to reflect region-specific period effects.

The causal interpretation of the intention-to-treat effects in this (and any DD or DDD) setting hinges on the common trend assumption. It seems plausible to assume that EC eligibility, i.e., a combination of a certain occupational SR combination in the parental couple and the federal state of residence, was of no importance pre-pandemic since there was no policy measure whatsoever related to such combination. To assess the legitimacy of this assumption, i.e., the exogeneity of EC eligibility, we provide two types of analyses: First, we regress EC eligibility on a variety of family sociodemographic characteristics. As expected, none of them appears to be statistically significantly associated with EC eligibility status (see Table A.2 in the Appendix). Second, we investigate pre-trends at the group level where possible. For the subgroup of mothers with children below the age of nine, we can utilize the cross-sectional AID:A surveys in 2009 and 2004 (Rauschenbach and DJI, 2012; Rauschenbach and DJI, 2018) to investigate group-specific pre-trends with respect to three of our outcomes: frequency of ‘becoming angry’, frequency of ‘speak about experiences’, and frequency of ‘speak about annoyance’.12 We group according to constellations of occupational SR in the parental couple and EC eligibility in the respective residence federal state to reproduce treatment and control groups as in the 2019 and 2020 data. The graphical display of outcome trends for these groups clearly shows almost identical trends for our EC-eligible treatment group and the main control group with SR in the parental couple that are not EC eligible between 2009 and 2014 (see Fig. A.2 in the Appendix). For completeness, we report trends for our second control group without any systemic relevant occupation in the parental couple, and for comparison, we additionally display the analogous figure with respect to 2019 and 2020 data for the subgroup of mothers with children below the age of nine.

### 4.2. Regression model of local average treatment effects

The local average treatment effect (LATE) refers to the effect of EC utilization for the subgroup of compliers among the EC-eligible population. The causal effects of eligibility and utilization are not necessarily the same in situations with non-compliance. Indeed, we expect a considerable amount of (two-sided) non-compliance in the setting of pandemic emergency childcare, e.g. due to protective parental behavior (which leads to EC-eligible parents not utilizing EC due to health concerns) or fuzzy implementation of the eligibility rules (which might result in EC utilization by non-eligible parents). In fact, we estimate an overall compliance rate of 32 percent in the first stage IV-LATE analysis (see Section 5.1 below). Typically, the ITT estimate might be seen as a lower bound on the average treatment effect (ATE), while the LATE estimate might provide an upper bound. The IV-LATE analysis is also useful to characterize compliers.

To directly examine the causal effects of EC utilization on parental well-being and negative parenting behavior, we exploit the fact that EC eligibility was determined by state-specific eligibility rules. We employ a first-differences model in the first stage, which—in two period panel models—is numerically equivalent to an individual fixed effects model. With respect to the regression model employed to estimate intention-to-treat effects, we exclude the second-level interactions (\(y_{rst}, \alpha_t, \theta_r\)) to yield a powerful first stage (Pischke, 2007, p.16). Overall, causal identification in this setup stems from the instrumental variable rather than the triple-difference approach. The analysis can be represented by the following system of equations:

\[ \Delta y_{rst} = \delta + \sigma \Delta \text{Utilization}_{rst} + \epsilon_{rst}, \]  

(3)

with the first stage given by:

\[ \Delta \text{Utilization}_{rst} = \omega + \delta \text{Eligibility}_{rst} + \epsilon_{rst}, \]  

(4)

where the first difference is calculated from the pre-pandemic year 2019 to 2020. EC utilization is obviously zero in 2019; we thus measure EC take-up, \(\Delta \text{Utilization}_{rst}\), as a dummy variable equal to 1 if parent i in federal state s reports having utilized EC during the first COVID-19 lockdown in Germany in spring 2020 (and 0 otherwise). The constant terms \(\delta\) and \(\omega\) represent first differences of the time effect. \(\text{Eligibility}_{rst}\) serves as an instrument for parents’ actual usage of EC. While exogeneity of EC eligibility conditional on individual fixed effects is sufficient for a causal interpretation of the intention-to-treat effects, identification of the causal effect of EC utilization on parental outcomes relying on EC eligibility as instrumental variable requires the additional assumption that EC eligibility affects parental well-being and parenting behavior only through the actual utilization of EC, and not directly in any other way (exclusion restriction). In the context of the first COVID-19 lockdown, this assumption appears rather plausible: while occupational systemic relevance per se might have been associated with factors that also influenced parental well-being and stress-levels (such as work in the health sector, potential exemptions from curfews and work-from-home-orders, or augmented infection risk exposure), the regional variation in EC eligibility regulations concerning the SR constellation in parental couples allows us to explicitly control for such factors. Note also, that no other policy measures were associated with the federal-state specific EC eligibility rules. Overall, there is no apparent alternative explanation for the EC eligibility effect that is unrelated to EC utilization and hence would challenge the exclusion restriction. Additional support for the exclusion restriction to hold is given by the placebo test presented in Appendix Table A.3. To perform this test, we exploit the fact that in federal state, emergency childcare was available for children above age 14 (or beyond 8th grade, see Appendix Table A.1). We reestimate model (1) – including individual fixed effects, without the second-level interactions – on a sample of parents with the youngest child in the household of age 15–17 that are hence not eligible for emergency childcare in any federal state. To estimate the placebo ITT effect, we nonetheless maintain the definition of EC eligibility in the parental couple as if children were of age below 14. A significant ITT effect on this specific sample would be a violation of the exclusion restriction that EC eligibility affects outcomes only through EC utilization. By contrast, we find no evidence of a significant ITT effect among parents with older children only, lending support to the exclusion restriction.

---

12 These outcomes have been collected in AID:A 2009 and AID:A 2014 in the identical wording as in AID:A 2019 and 2020, however, with a 4-point instead of a 6-point response scale and the questions were only posed to mothers with children under age 9.

5. Results and discussion

5.1. Intention-to-treat effects

We use model (1) to estimate the intention-to-treat effects of the provision of EC on parental well-being and parenting behavior outcomes. These estimates inform about EC provision in its acute phase, when the occupation-based eligibility rules described in Section 2 (Table 1) were in place, abstracting from the effects of subsequently extended emergency childcare.

Table 3 presents the main results with respect to parental well-being measures and indicators of negative parenting behavior. For each outcome, we present the estimated coefficient β—based on individual fixed effects regressions—as the double-difference estimator in Panel A, and the triple-difference estimator in Panel B of Table 3. Panel C reports a gender interaction of the triple-difference estimator to investigate treatment heterogeneity for mothers and fathers.16

---

16 We find no further effect heterogeneity with respect to various sociodemographic characteristics (household income, parents’ level of education, migration background, number of children, age of children, share of male children) or pre-pandemic psychological well-being of parents. These results are available from the authors upon request.

The double-difference results in Panel A indicate that among parents with at least one SR occupation among the parental couple, EC-eligible and non-eligible parents experienced similar decreases in parental well-being between 2019 and 2020. With respect to negative parenting behavior, it appears that while non-EC-eligible parents report strong increases in “harsh parenting” in terms of “quickly becoming angry if children don’t do as I say”, the EC-eligible are significantly less prone to such increases. These effects are marginally statistically significant. However, they cannot isolate the causal effect of EC eligibility, as there may have been other state-specific shocks to parental stress levels (e.g., due to other COVID-19 measures at the state-level or regional infection dynamics). We hence augment the double-difference model to examine this possibility by taking advantage of the fact that parents without any occupational systemic relevance were not granted access to EC in the acute lockdown period. This allows us to use outcome changes for
this group to control for unobserved state-specific shocks via a triple-difference technique.

The triple-difference results presented in Panel B of Table 3 confirm that overall, access to EC did not considerably affect parental life satisfaction or partnership satisfaction. However, we estimate a positive effect on well-being according to the WHO-5 index by 0.429 of one standard deviation, which is statistically significant at the 5-percent level. To classify the effect size, we compare it to the gender difference between mothers and fathers, which amounts to 0.177 of a standard deviation in the year 2019. Hence, our estimated effect is 2.4 times as large as the average gender difference in the WHO-5 index.

With respect to parenting behavior, it appears that EC was effective at preventing increases in “harsh parenting” in terms of ‘becoming angry’. The estimated effects are statistically significant at the 5-percent level, and indicate that being EC-eligible decreases the frequency of ‘becoming angry’ by 0.423 of one standard deviation. To classify the effect size, we again compare it to the average gender difference between mothers and fathers (0.120 of a standard deviation in the year 2019). Our estimated effect is 3.5 times as large as the average gender difference for ‘becoming angry’. Effect sizes of WHO-5 well-being and harsh parenting in terms of ‘becoming angry’ are hence rather similar in size. Note again that these are short- to medium-term effects, measured as of September/August 2020, i.e. in a phase of “re-opening” and relative relaxation of COVID-related policy measures. Immediate effects during the acute lockdown in March/April 2020 are likely to have even been stronger.

Comparing double- and triple-difference results seems to suggest that state-specific shocks are positively correlated with both EC eligibility and parental stress. In fact, we observe that federal states with higher levels of SARS-CoV-2 infection rates just before the first lockdown seem to have provided relatively more generous access to emergency childcare (see Fig. A.3 in the Appendix). Federal states with lower infection levels regulated access to emergency childcare more strictly.

Gender interactions presented in Panel C of Table 3 reveal statistically significant gender differences only for negative parenting behavior with respect to ‘punishing harder’. Here, EC appears to have affected fathers only, in that it decreased the frequency of ‘punishing children harder than merited’ by 0.401 of one standard deviation. Interestingly, we find a similar gender pattern when investigating positive parenting behavior in terms of child-centered communication (see Table A.4 in the Appendix).17 It is only fathers that appear to respond to EC with increased frequencies of ‘speaking with the child about his/her experiences’ (by 0.407 of one standard deviation) and ‘speaking with the child about things that annoy or burden him/her’ (by 0.536 of one standard deviation), while control-group parents show significant decreases in the frequency of child-centered communication. One explanation for this finding could be that while mothers and fathers similarly express negative emotions (‘becoming angry’), fathers are relatively more prone to punitive behavior (‘punishing harder’, limiting positive parenting) since it is less socially undesirable for males than for females. However, previous research points to either mothers engaging in more disciplinary actions than fathers (Patterson, 1982; Mulherin and Passman, 1981) or only limited gender differences in punitive behavior (Lyttton and Romney, 1991). Overall, there is more research needed to uncover the gender-related mechanisms at play.

Tables A.5 to A.7 in the Appendix provide three types of robustness checks for our main outcomes. First, we reproduce the triple-difference results of Panel B of Table 3 (and additionally the gender interaction for the outcome ‘punish harder’) based on weighted regressions employing a combination of AID:A design weights at the household level and “staying probability” weights at the individual level (Table A.5 in the Appendix). Second, we re-run the analyses on a sample that includes the two federal states that applied an “all access” EC eligibility rule in the acute lockdown (Hamburg and Saarland), which we exclude in our main analysis sample (see Table A.6 in the Appendix). Third, we show results based on an alternative imputation of partners’ occupational systemic relevance, which is regression-based, employing federal state and occupation fixed effects (see Table A.7 in the Appendix). Overall, the results on harsh parenting behavior remain (sometimes marginally) statistically significant, and are qualitatively similar to our preferred estimates. This is also the case for estimates with respect to WHO-5 well-being, except for the weighted regressions, where the effect becomes statistically insignificant (see Table A.5 in the Appendix).

Given the categorical nature of the dependent variable ‘becoming angry’, we also investigate which frequency categories are most affected. That is, does the EC effect largely stem from changes in modest frequencies in ‘becoming angry’ or rather from frequency changes among already somewhat ‘angry’ parents? Table A.8 in the Appendix reports our key triple-difference results on ‘becoming angry’ from Panel B of Table 3 with respect to dichotomized outcome variables indicating different groupings of the frequency categories: the lowest frequency (“never”), the two lowest frequencies (“never” and “seldom”), the three highest frequencies (“often”, “very often” and “(almost) always”), and the two highest frequencies (“very often” and “(almost) always”).18 The overall effect appears to largely originate in movements from the upper two frequency categories “very often” and “(almost) always” toward the category “often”, as well as movements from “sometimes” toward the lowest two frequencies of “never” or “seldom” becoming angry. This might point towards movements within rather than across the margins of low and high frequencies.

Concerning mechanisms, one explanation might be the time spent with children. Since parents without access to EC spent more time with their children during lockdown than EC-eligible parents, this may contribute to increase the likelihood of harsh parenting behavior. However, the relationship between children’s exposure to parents and the frequency of harsh parenting behavior has to our knowledge not been established in the empirical literature. Another potential explanation might be that – while all parents experienced a similar drop in well-being in the pandemic – parents without EC experienced relatively stronger job-related or financial worries due to reductions or shifts in working hours, which may be relatively more prone to translate into harsh parenting behavior. However, interactions with reported financial restrictions due to the pandemic and worries about job loss do not support this channel. With respect to ‘becoming angry’ we find no significant differences in estimated effects that are related to whether parents state financial restrictions or job loss worries.19

5.2. Local average treatment effects

The intention-to-treat results show how EC availability during the first COVID-19 lockdown in Germany affected parental well-being and negative parenting behavior. To interpret these results in a setting, where we expect a considerable amount of two-sided non-compliance, it is—as a first step—important to understand the extent and pattern of EC

17 Note that survey items on positive parenting behavior were child-specific in 2019 and collected only for children above the age of two. For this reason, we report results on this subsample and take the mean across children to make these observations comparable to the 2020 survey where these items were parent-specific. The survey questions read as follows: “How frequently do the following occur? I speak with the child about his/her experiences” (1 “never” to 6 “(almost) always”). “How frequently does the following occur? I speak with the child about things that annoy or burden him/her” (1 “never” to 6 “(almost) always”). Items regarding child-centered communication have been adapted from the Supportive Parenting Scale by Simons et al. (1992) and are well-established measures in previous AID:A panel studies (see e.g. Barquero and Geier, 2008; Walper and Grieß, 2013).

18 There are too few observations in the highest frequency category (“almost) always)” to allow its separate investigation.

19 Results are available from the authors upon request.
take-up (see discussion in Section 4.2). First, we quantify the relationship between EC availability and EC utilization by estimating the first stage model (4) based on Sample B.\textsuperscript{20} We estimate the coefficient on eligibility (\(\hat{\delta}\)) to be about 0.32 with a standard error of 0.08. This estimate implies a 10 percentage point increase in EC eligibility among parents induces (an additional) 3.2 percent of parents to take up EC. To roughly understand what type of parents utilize EC when they are eligible (compliers), we estimate Eq. (4) separately for different types of parents. We partition Sample B sequentially by regional population size, parental education, mothers’ labor market involvement, and age of the youngest child. Maternal remote work during lockdown, pre-pandemic division of care work, pre-pandemic parental well-being and parenting—that is, we split the sample in two, with one part including values equal to or below the median, and another for values above the median.

Column (1) of Table A.9 in the Appendix displays the median value of each characteristic. Column (2) reports the proportion of the sample that falls above the respective median value. Columns (3) and (4) show the distribution of compliers across the two subgroups (below or equal to the median, and above median) for each characteristic. Following Angrist (2004) and Akerman, Gaarder, and Mogstad (2015), the proportion of the compliers of a given type is calculated as the ratio of \(\hat{\delta}\) for that subgroup to the \(\hat{\delta}\) in the overall sample, multiplied by the proportion of the sample in the respective subgroup.

We see that EC is not randomly adopted within the group of eligible parents. Compliers are slightly underrepresented among families that live in relatively more urban areas (with more than 50,000 inhabitants), and strongly underrepresented among parents with a university degree, in parental couples where mothers work more than 20 hours a week, and in families with relatively older children (i.e., the youngest child is above the age of three). The underrepresentation of compliers among the high-educated might in part be explained by the fact that the feasibility of working-from-home strongly increases with an academic degree (Alipour, Falck, and Schüller, 2020). This conjecture is corroborated by the finding that compliers are also underrepresented in families where mothers did work more than 50 percent of their work time remotely during the lockdown in March/April 2020. Interestingly, compliers are overrepresented among families in which fathers are relatively strongly involved in housework and childcare, and among parents with relatively stronger partnership satisfaction and psychological well-being. Compliers are underrepresented among parents that state relatively more frequent harsh parenting in the pre-pandemic period.

In the following, we focus on the outcomes of harsh parenting behavior, where the intention-to-treat regressions yield robustly statistically significant “reduced form” effects.\textsuperscript{21} We deem the results with respect to WHO-5 well-being not entirely robust due to the lack of statistical significance in the double-difference as well as in the weighted regressions. In fact, also the LATE effects are not statistically significant for WHO-5 (see Table A.10 in the Appendix).

Invoking the exclusion restriction conditional on individual fixed effects, we estimate how the utilization of EC affects the incidence of harsh parenting behavior among compliers. We approach the presentation of the LATE effects in a stepwise manner, taking the ITT effects presented in Table 3 as a starting point. Column (1) of Table 4 repeats the intention-to-treat effects reported in Table 3, as resulting from a first-differences regression and now without second-level interactions.\textsuperscript{22} In comparison with Table 3, the ITT effects without second-level interactions are about half the size, but are still statistically significant at the 5-percent level.\textsuperscript{23} Column (2) of Table 4 reports intention-to-treat effects estimated in the same way using Sample B instead of Sample A. ITT effects appear to increase in size and in statistical significance when families with relatively older children (i.e., with the youngest child being of school-age) are excluded from the sample. The specification without second-level interactions allows for a neat comparison of outcome changes between EC-eligible and non-eligible parents, since the estimated constant now indicates the average outcome changes for non-eligible parents. Hence, we can observe that the frequency of ‘becoming angry’ significantly increases by about 0.436 (0.443) of one standard deviation between 2019 and 2020 for non-EC-eligible parents, and that this increase is effectively reduced by about half (by 0.164 and by 0.281 of one standard deviation respectively for Sample A and B) for EC-eligible parents. Instead, with respect to ‘punishing harder’, we observe much smaller increases for the non-EC-eligible parents (0.044 and 0.121 standardized effects), which are not statistically significant for Sample A, and only marginally statistically significant at the 10-percent level for Sample B. There are also no considerable differences in outcome changes for EC-eligible parents.

Column (3) of Table 4 presents estimates of Eq. (2) based on OLS. The OLS estimate is informative regarding the correlation between EC utilization and our outcome of interest, without any distinction made between EC utilization during the acute lockdown and utilization of extended EC during the subsequent re-opening. Interestingly, in this case, there appears to be no statistically significant association between EC utilization (including during extended EC) and the frequencies of harsh parenting behavior.

Column (4) of Table 4 reports estimates based on IV estimation of Eq. (3). In contrast to the OLS estimate, with IV we estimate the effect of EC utilization on compliers, i.e., parents who utilize EC due to their SR-constellation based eligibility status. These compliers are most likely parents that had already taken up emergency care by the beginning of the lockdown. In turn, non-EC eligible parents that took up EC during the phase of extended EC are not compliers in this setup. The first stage is strong, with a Kleibergen-Paap rk Wald F-statistic of 16.15 on the excluded instrument, which means weak instrument bias is not a concern. The IV estimate with respect to ‘becoming angry’ is statistically significant at the 5-percent level, and suggests that EC utilization due to eligibility based on parents’ occupational systemic relevance was effective at preventing increases in negative and potentially harmful parenting behavior that would have happened in the absence of EC. Specifically, EC utilization reduced the frequency of ‘becoming angry’ by 0.876 of one standard deviation. As expected, the effect size is considerably larger among compliers than among all EC-eligible parents, where eligibility is associated with a 0.281 standard deviation decrease in the frequency of ‘becoming angry’ (see Column 2). It also becomes evident that EC utilization among the EC-eligible can entirely prevent the increase in the frequency of ‘becoming angry’ that non-EC eligible parents experienced (by 0.606 of one standard deviation). In contrast, with respect to ‘punishing harder’, there appears to be no significant effect of EC utilization on compliers.

Column (5) finally reports on an investigation of potential gender differences in the IV estimates. It turns out that while there is no significant difference in EC effects on ‘becoming angry’ between fathers and mothers, the interaction with parental gender reveals that EC utilization significantly reduced the frequency of ‘punish harder’ for fathers, but not for mothers. The decrease in fathers’ harsh parenting in terms of ‘punishing harder’ is statistically significant at the 5-percent level, and is of substantial size (a standardized effect of 1.009). Note, \textsuperscript{24}Note that we now restrict the sample to families with children of preschool age or younger, since there is no information on EC utilization for school children in the data.

\textsuperscript{21} We report LATE estimates on the remaining outcomes in Table A.10 in the Appendix. They are statistically insignificant throughout. There are also no significant gender differences.

\textsuperscript{22} By excluding second-level interactions, we assume that, were it not for differences in EC eligibility rules (conditional on parent time-invariant characteristics), outcome levels would have been similar for different SR constellations across federal states and that outcome changes would not have varied across federal states or across SR constellation groups.

\textsuperscript{23} This finding mirrors the previous comparison of double- and triple-difference results suggesting that not controlling for state-specific shocks results in a downward bias, since these shocks are positively correlated with both EC eligibility and parental stress.

Source: AID:A 2019, AID:A Corona Add-on 2020; own calculations.

Notes: All outcome measures are standardized to have a mean of zero and a standard deviation of one. 'Become Angry': “How frequently does the following occur? I quickly become angry when my child(ren) don’t do as I say” (1 "never" to 6 "almost always”). 'Punish Harder': “How frequently does the following occur? I punish my child(ren) harder than what they merit.” (1 "never” to 6 "almost always”). Columns 4 and 5: EC usage is instrumented by eligibility to EC during the acute lockdown based on parental SR constellation. Rwf: Kleibergen-Paap rk Wald F statistic. Sample A: families with children below age 12. Sample B: families with children of preschool-age or younger. Cluster-robust standard errors at household level.

*** p < 0.01
** p < 0.05
* p < 0.1

However, that the LATE estimate might not be unconditionally generalizable to the full population since complier analysis has shown that not all EC-eligible parents utilize EC and that compliers are a particular group among EC-eligible parents. Another indication for external validity is the comparison of average outcomes of always-takers and compliers among those that utilized EC, and the comparison of average outcomes of never-takers and compliers among those that did not utilize EC. The average outcomes of those complier groups are not observed directly, but can be calculated under the assumption of instrument exogeneity and monotonicity (see Angrist, 2004). With respect to our main outcome ‘becoming angry’, comparing average standardized outcomes of always-takers and compliers among those that utilized EC (0.578 vs. -0.336) as well as average outcomes of never-takers and compliers among those that did not utilize EC (0.082 vs -0.127) yields again the conclusion that the LATE estimate might not be indicative of average effects for compliance types other than compliers.

Comparing ITT and LATE estimates, we consider that the ITT estimate might be typically seen as a lower bound and the LATE estimate as an upper bound on the average treatment effect (ATE). With respect to ‘becoming angry’, the ATE might hence range between 0.436 and 0.876 of a standard deviation.

### 6. Concluding remarks

Having carried out a first rigorous evaluation of emergency childcare (EC) policies during the first COVID-19 lockdown in Germany in early 2020, we find that EC was not able to permanently shelter families from a considerable reduction in parental well-being. However, the provision of EC was effective in diminishing increases in harsh parenting among EC-eligible parents. This effect of EC is more pronounced in families with children of preschool-age or younger, and completely cancels out increases in harsh parenting among compliers.

We evaluate effects 4 to 5 months after the first COVID-19 lockdown in Germany, and hence provide evidence on the short- to medium-term consequences, rather than the immediate impact of emergency childcare. Further research is needed to assess the mechanisms behind the gendered impact of EC on ‘punishing harder’ and child-centered communication, where we find effects exclusively for fathers.

Overall, our results disentangle effects caused directly by school and daycare closures from general effects of the pandemic, since among families with childcare usage we compare those who experienced or—due to EC—did not experience a complete disruption of external childcare provision. Thus, we conclude that, while decreasing parental well-being is likely to be a general pandemic effect rather than a specific effect of the closures, the observed increase in negative and potentially harmful parenting behavior is largely directly caused by school and daycare closures. Negative parenting behavior is thus a likely mechanism for the substantial detrimental effects of the pandemic on mental health of children and adolescents observed in Germany (e.g. Ravens-Sieberer et al., 2022).

An important limitation of our study is that—given the data at hand—we can only provide somewhat isolated effects on parental well-
being and parenting behavior, and not a comprehensive view of the impacts of school and daycare closures. To draw meaningful policy conclusions, impacts on e.g. long-term child development, health risks for parents and children, or the rate of new infections (see e.g. Dehning et al., 2020; Brauner et al., 2021) must be additionally considered.

Acknowledgments

We thank the guest editor Margherita Fort and three anonymous referees for helpful comments. We thank Stefan Bauernschuster, Christina Boll, Vincenzo Galasso, Malte Borghorst, Mariana Grgic, Susanne Kuger, Ulrich Pötter, Claudia Zerle-Elßäßer, our colleagues at DJI and participants of the 2021 CESifo Area Conference on Public Economics, the DJI online conference “Aufwachsen in Deutschland 2019. Alltagswelten von Kindern, Jugendlichen und Familien”, the 2021 European Sociological Conference, the 2021 European Association of Labour Economics Conference, the North American Meeting on the Urban Economics Association and the colloquium of the Bamberg Graduate School of Social Science for valuable discussions and suggestions. We are grateful to Kirsty Weiler for editorial advice, Stephan Heuberger for research assistance, and the Corona-KiTa-Study Team for providing us with information on utilized daycare capacity data from the DJI-RKI (2020) report. This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors. Declarations of interest: none.

Appendix

Figures A.1–A.3 and Tables A.1–A.10.

Fig. A.1. Emergency Childcare Policies in the German Federal States during the first COVID-19 Lockdown. Sources: Decrees or corresponding press releases by the respective federal state (see Table 1 and Table A.1).
Panel A. Frequency of ‘Becoming Angry’

- No parent SR
- At least one parent SR, not EC eligible
- At least one parent SR, EC eligible

Panel B. Frequency of ‘Speak about Experiences’

Notes: Sample of mothers with children below the age of nine. Observations in “all access” federal states are excluded. Trends are displayed for three separate groups: mothers with SR in the parental couple that are EC eligible (treatment group, black line), mothers with SR in the parental couple that are not EC eligible (main control group, grey line), and mothers without SR in the parental couple (second control group, dashed grey line).

To define occupational SR in the parental couple, individual SR of mothers and their partner has been predicted in the AID:A 2019 data based on occupations (4-digit ISCO-08) and federal state of residence and subsequently imputed in the AID:A 2009 and AID:A 2014 data.

‘Become Angry’: “How frequently does the following occur? I quickly become angry when my child(ren) don’t do as I say.”

‘Speak about Experiences’: “How frequently does the following occur? I speak with the child about his/her experiences.”

‘Speak about Annoyances’: “How frequently does the following occur? I speak with the child about things that annoy or burden him/her.”

Table A.1
Emergency Childcare Policies in the German Federal States during the first COVID-19 Lockdown.

| State                     | Eligibility rules based on parents’ occupations | Eligibility limit according to age or grade of children |
|---------------------------|-------------------------------------------------|--------------------------------------------------------|
| Baden-Württemberg        | 2-parent rule                                   | up to 6th grade                                       |
| Bavaria                  | mixed rule                                      | up to 6th grade                                       |
| Berlin                   | 1-parent rule                                   | up to 6th grade                                       |
| Brandenburg              | 2-parent rule                                   | no restrictions                                       |
| Bremen                   | mixed rule                                      | up to 8th grade                                       |
| Hamburg                  | all access                                      | up to age 14                                         |
| Hesse, link1, link2      | 1-parent rule                                   | up to 6th grade                                       |
| Lower Saxony             | 1-parent rule                                   | up to 8th grade                                       |
| Mecklenburg-Vorpommern   | 2-parent rule                                   | up to 6th grade                                       |
| North Rhine-Westphalia   | 2-parent rule                                   | up to 6th grade                                       |
| Rhineland-Palatinate     | 1-parent rule                                   | up to 7th grade                                       |
| Saarland                 | all access                                      | up to age 12                                         |
| Saxony                   | mixed rule                                      | up to 4th grade                                       |
| Saxony-Anhalt            | 2-parent rule                                   | up to age 11                                         |
| Schleswig-Holstein       | mixed rule                                      | up to 6th grade                                       |
| Thuringia                | 2-parent rule                                   | up to 6th grade                                       |

Sources: Decrees or corresponding press releases by the respective federal state (see hyperlinks in the first column).

Notes: “2-parent rule”: both parents have to work in a systemically relevant occupation to be eligible for EC. “1-parent rule”: at least one parent has to work in a systemically relevant occupation to be EC eligible. “Mixed rule”: parents have to either work both in a systemically relevant occupation or at least one parent works in an occupation in the health and care sector to gain access to EC. “All access”: parents are encouraged to keep their children at home, but access to EC is not further regulated. Lower Saxony and Schleswig-Holstein adjusted their regulations after the first week of lockdown. We employ the adjusted regulations. The eligibility rules summarized here concern the first phase of emergency childcare. Eligibility expanded in the subsequent phase of extended emergency childcare, whereby all federal states except Thuringia (where the 2-parent rule remained in place) applied the 1-parent rule.

Table A.2

Notes: This table displays results of a placebo analysis on a restricted sample of parents with the youngest child in the household of age 15 – 17, hence not eligible for emergency childcare in any federal state (see Table A.1). All outcome measures are standardized to have a mean of zero and a standard deviation of one. ‘Life satisfaction’: “How satisfied are you with your life, all things considered?” (1 "not at all satisfied" to 6 "very satisfied"). ‘Partnership satisfactions’: “Overall, how satisfied are you with your relationship?” (1 "not at all satisfied" to 6 "very satisfied"). The WHO-5 Well-being Index ranges from 0 “absence of well-being” to 100 “maximal well-being”. ‘Become Angry’: “How frequently does the following occur? I quickly become angry when my child(ren) don’t do as I say” (1 "never" to 6 "almost always"). ‘Punish Harder’: “How frequently does the following occur? I punish my child(ren) harder than what they merit.” (1 "never" to 6 "almost always"). Cluster-robust standard errors at household level.

Notes: We partition the IV sample (Sample B: families with a child of preschool-age or younger) sequentially by regional population size, parental education, mother’s labor market involvement, age of the youngest child, maternal remote work during lockdown, pre-pandemic division of care work, pre-pandemic parental well-being and parenting (above and below median of each characteristic). Column (1) displays the median value of each characteristic. Column (2) reports the proportion of the sample that falls above the respective median value. Columns (3) and (4) show the distribution of compliers across the two subgroups (below or equal to the median and above median) for each characteristic. The proportion of compliers of a given type is calculated as the ratio of δ for that subgroup to the δ in the overall IV sample (Sample B), multiplied by the proportion of the sample in the respective subgroup (see also Angrist, 2004, p.C69).

Table A.10
LATE Effects on Parental Well-Being for Parents with Children of Preschool Age or Younger. First-Differences Estimation.

|                        | Life Satisfaction | Partnership Satisfaction | WHO-5 |

Notes: EC usage is instrumented by eligibility to EC during the acute lockdown based on parental SR constellation. All outcome measures are standardized to have a mean of zero and a standard deviation of one. ‘Life satisfaction”: “How satisfied are you with your life, all things considered?” (1 "not at all satisfied" to 6 "very satisfied"). ‘Partnership satisfactions”: “Overall, how satisfied are you with your relationship?” (1 "not at all satisfied" to 6 "very satisfied"). The WHO-5 Well-being Index ranges from 0 “absence of well-being” to 100 “maximal well-being”. Cluster-robust standard errors at household level.
