ABSTRACT

Only a few molecular clouds in the Solar Neighborhood exhibit the formation of only low-mass stars. Traditionally, these clouds have been assumed to be supported against more vigorous collapse by magnetic fields. The existence of strong magnetic fields in molecular clouds, however, poses serious problems for the formation of stars and of the clouds themselves. In this Letter, we review the three-dimensional structure and kinematics of Taurus—the archetype of a region forming only low-mass stars—as well as its orientation within the Milky Way. We conclude that the particularly low star-formation efficiency in Taurus may naturally be explained by tidal forces from the Galaxy, with no need for magnetic regulation or stellar feedback.

Key words: Galaxies: kinematics and dynamics – ISM: clouds – kinematics and dynamics – Stars: formation

1 INTRODUCTION

Few nearby molecular clouds (e.g. Taurus, Chamaeleon I and II) are observed to form only low-mass stars. Assuming a universal initial mass function, the lack of high-mass young stars in these regions indicates a low overall star-forming rate compared with clouds like Orion where both low- and high-mass stars are actively being formed. Traditionally, the clouds forming only low-mass stars have been assumed to be supported against more vigorous collapse by magnetic fields. In such a scheme, stars can form only after substantial magnetic flux has been removed locally via ambipolar diffusion (e.g., Shu et al. 1987). The Taurus Molecular Cloud (TMC) is often cited as the archetype for this picture of isolated, low-mass star formation.

There are, however, some difficulties with this scenario. On the one hand, strong magnetic fields ought to prevent the formation of molecular clouds by large-scale compressions in the first place (see Hartmann et al. 2001). In addition, there is a problem with the synchronization of star formation along large distances. While molecular clouds have dynamical timescales of the order of 10–20 Myr, most active star-forming regions (i.e. those still containing molecular gas) have populations with ages $\lesssim$ 3 Myr (Hartmann et al. 2001). The lack of old stars associated with molecular clouds (the so-called post-T Tauri problem, see Herbig 1973; Herbig et al. 1986) has been explained in terms of rapid assembling of molecular clouds by large-scale flows, which may be able to trigger star formation over large regions almost simultaneously. Such a rapid assembling of molecular clouds and synchronized events of star formation over large distances require magnetic fields to not be dominant (Hartmann et al. 2001). Moreover, the ambipolar diffusion timescale is not unique. It depends, among other parameters, on the ionization fraction, which in turn depends on the precise local shielding conditions. Differences in the degree of ionization and magnetic field intensities should introduce an unobserved spread of at least several Myr in the onset of star formation. This brings us back to the post-T Tauri problem (Ballesteros-Paredes & Hartmann 2007).

Different numerical work has examined the picture of rapid molecular cloud assembling from different points of view and found it to be a viable mechanism (see Ballesteros-Paredes et al. 2007, and references therein). An important difficulty, however, is the low star formation efficiency observed in actual molecular clouds, compared with those reported in simulations. As discussed by Heitsch & Hartmann (2008), most simulations are performed in closed boxes, with no stellar energy feedback. In such a situation, the amount of mass in collapsed ob-
objects after one crossing time is usually large, with values between 10% and 30%, depending on the mass and the level of turbulence of the model (Klessen et al. 2000; Vázquez-Semadeni et al. 2003, 2005). In comparison, typical values of the star formation efficiency observed in molecular clouds is only a few percent (Myers et al. 1988). When feedback from massive stars is included in the simulations, the measured efficiencies are significantly smaller (Passot et al. 1995), suggesting that massive stars are a key ingredient in regulating the efficiency of star formation (see also Ballesteros-Paredes 2004, and references therein).

In regions where no massive stars are formed, however, a different mechanism is clearly required. And since magnetic regulation brings a number of additional problems, it is worth looking for alternative possibilities. Recently, Ballesteros-Paredes et al. (2003 = Paper I) have analyzed the complete gravitational content of molecular clouds within a given spiral galaxy. They write the total gravitational energy of a molecular cloud, \( W \), as follows:

\[
W = -\frac{1}{2} \int_V \rho \Phi_{\text{cloud}} dV - \int_V \frac{\partial \Phi_{\text{ext}}}{\partial x_i} dx_i dV,
\]

where \( \rho \) is the density, \( \Phi_{\text{cloud}} \) is the gravitational potential due to the mass of the cloud, i.e., the mass inside its volume \( V \), \( \Phi_{\text{ext}} \) is the gravitational potential due to the mass outside the cloud, and \( x_i \) is the \( i \)-th component of the position vector. The first term on the right is the gravitational energy \( E_{\text{grav}} \), while the second is the energy due to the mass outside of the cloud, which we call the tidal energy. This second term may cause a compression or a disruption of molecular clouds, depending on their size, position and orientation within the host galaxy. Thus, tidal interactions may play a significant role in the overall stability of molecular clouds, and, therefore, on the efficiency of star formation within them.

In this Letter, we investigate the role that tidal interactions might play in the regulation of star formation in the TMC. In §2 we examine the three-dimensional structure and the orientation of Taurus within the Milky Way using recent data. We then calculate the relative contribution of self-gravity and tidal interactions for such a configuration (§3) and discuss our results in §4. The conclusions are given in §5.

2 THREE DIMENSIONAL STRUCTURE OF TAURUS

In CO maps, the TMC extends for about 10 degrees on the sky, with filaments that have aspect ratios between 5:1 and 10:1 (e.g., Goldsmith et al. 2008). It has a total molecular mass between \( 10^{4} \) and \( 2.4 \times 10^{4} M_\odot \) (Goldsmith et al. 2008) and is located roughly towards the Galactic anti-center at \( (l, b) \sim (170^\circ, -15^\circ) \) (Ballesteros-Paredes et al. 2004). The obtained distances range from about 160 pc for HP Tau, near the eastern edge of the complex at \((l, b) \sim (175^\circ, -16^\circ)\) (Torres et al. 2004), down to about 130 pc for the closest stars, Hubble 4 and HDE 283572, in the western part of the TMC at \((l, b) \sim (170^\circ, -15^\circ)\) (Torres et al. 2007). This situation is quite unlike that in the core of Ophiuchus (Loinard et al. 2008a) or the Orion nebula (Menten et al. 2007) where different stars are found at very similar distances.

The properties mentioned above indicate that it is appropriate to model the TMC as a \( 10^4 M_\odot \) elongated filament (a prolate spheroid) centered at a distance of 145 pc from the Sun in the direction \((l, b) = (172.5^\circ, -15^\circ)\) (see Fig. 1 for a schematic view). This places the TMC about 37.5 pc below the Galactic plane. The long axis of the spheroid was taken to be of 32.37 pc long and, assuming an angular width for the cloud of about 5\(^\circ\), the short axes are 5 pc in length. The density of the spheroid was taken to be constant; for our choice of parameters, its value is \( n = 405 \text{ cm}^{-3} \).

We performed an energetics analysis similar to that presented in Paper I, but with one important difference. In our previous work, every parcel of the test cloud had a velocity given by the circular velocity. As most nearby star forming cloud, however, the TMC has a substantial peculiar velocity (Torres et al. 2004). Therefore, although the calculation of the tidal energy \( W_{\text{ext}} \) is performed in the standard of rest of the center of the spheroid, the effective potential must involve the peculiar velocities of the filament. In order to account for those velocities, we calculated the components of the peculiar velocities \((u, v, w)\) using radial velocities from the CO observations (Ungerechts & Thaddeus 1987, see also Figs. 2 and 3 in Ballesteros-Paredes et al. 1999), and the proper motions of the stars reported by Torres et al. (2004, 2007). We note that the proper motions have been determined with a very good accuracy (± 0.15 mas yr\(^{-1}\) in the worst case). However, since the line profile of the gas has some spread around the maximum intensity, we have used radial velocities (express relative to the Local Standard of Rest) ranging from 5 to 5.5 km sec\(^{-1}\) near the eastern edge of the cloud, and from 5.5 to 6 km sec\(^{-1}\) for the western part.

Figure 1. Schematic view of the TMC, according to the distances and positions reported by Loinard et al. (2003, 2007); Torres et al. (2007, 2009).
3 RESULTS

As in Paper I, the gravitational potential used to calculate the tidal energy \( W_{\text{ext}} \) includes a Galactic axisymmetric background potential that represents a bulge, a flattened disk, and a massive halo, and a bisymmetric potential describing a logarithmic spiral pattern. Our choice of parameters describing this potential reproduces, in particular, the Oort constants, the rotation curve and the local escape velocity (see Pichardo et al. 2003, and references therein). The exact position of the TMC with respect to the Galactic stellar spiral arms is not well known. Thus, we have calculated the ratio between the tidal and the gravitational energy, \( W_{\text{ext}}/E_{\text{grav}} \), as a function of galactocentric angle, \( \theta \) (Fig. 2). The different curves are the results of our calculations assuming a slightly different radial velocities, in order to account for the scatter in the CO emission (see Paper I for details), it is straightforward to scale it to a different total mass.

Fig. 2 shows some important points. First of all, the ratio \( W_{\text{ext}}/E_{\text{grav}} \) is always negative, with values between \(-3\) and \(-3.6\) (shaded region), depending on the detailed velocity field assumed for the cloud. This indicates that the tidal energy \( W_{\text{ext}} \) acts against the gravitational energy, i.e., by trying to disrupt the cloud. Second, for this configuration, the tidal energy is larger than the gravitational energy for any azimuthal angle. Third, even close to the spiral arms (\( \theta \sim 15^\circ \) in our figure), an elongated cloud highly aligned with the galactocentric radius will also be disrupted.

We have performed the same calculations for smaller clumps at the same position, but with different aspect ratios, densities, and sizes. Our results indicate that for smaller and denser regions, the situation is reversed and the gravitational energy exceeds the tidal energy by factors of 10 to \( 10^3 \), depending on the properties of the clumps/cores. The situation considered in these calculations correspond to individual clumps within the TMC, such as Heiles Cloud 2, or Lynds 1495 (see Goldsmith et al. 2008, for details), or to individual dense cores like TMC-1C or Lynds 1517. This means that if the volume filling factor of the gas is smaller than unity, the small, compact, dense fragments will collapse, but the cloud as a whole will not. By disrupting the cloud, tidal forces prevent global collapse.

4 DISCUSSION

As mentioned in Paper I, magnetic fields and massive stars have been the usual mechanisms invoked to explain the low efficiency of star formation observed in star-forming regions. In the case of Taurus, feedback by massive stars clearly cannot be invoked since there are no such stars. Large magnetic fields, on the other hand, are difficult to reconcile with the synchronized star formation observed in molecular clouds in the Solar Neighborhood.

About ten years ago, it was proposed that molecular clouds in general, and Taurus in particular, could be produced by converging large-scale flows (Ballesteros-Paredes et al. 1999), explaining how star formation can occur simultaneously in dynamically disconnected regions. Hartmann et al. (2001) pointed out that the interstellar gas in the Solar Neighborhood becomes gravitationally unstable at the same time that it becomes molecular, and that typical magnetic fields are not strong enough to inhibit rapid molecular cloud and star formation. More recently, different authors have reported that turbulent motions may have a gravitational origin (Burkert & Hartmann 2004; Ballesteros-Paredes 2006; Vázquez-Semadeni et al. 2007; Hartmann & Burkert 2007; Field et al. 2008; Heitsch & Hartmann 2008). This revived the idea originally proposed by Goldreich & Kwan (1974) that the supersonic linewidths have a gravitational origin. In particular, Vázquez-Semadeni et al. (2007) showed that collapsing clouds develop a “virial” type relationship in which kinetic and gravitational energy are within a factor of two of each other. Moreover, Heitsch & Hartmann (2008) have found that, although molecular clouds and their substructures are formed by colliding turbulent flows, some degree of gravitational contraction must occur along the direction perpendicular to the collision of the streams, to allow molecular cloud and star formation.

All the work mentioned above suggests that molecular clouds must be, to some degree, in a state of global collapse that typical magnetic fields cannot detain. In this situation, magnetic support cannot be invoked to regulate star formation, and massive stars are seemingly the only agents able to keep the star formation efficiency at a reasonably low value. But what regulates star formation in clouds, like Taurus, which do not harbor massive stars?

The results of the previous section allow us to propose a...
solution. Like every known large molecular cloud, the TMC has a mass much larger than its Jeans mass, so it could be collapsing vigorously. Because of its position and orientation within the Milky Way, however, it appears to suffer significant large-scale tidal disruptions. This ought to prevent global collapse and limit the efficiency of star-formation. Note, however, that tidal disruption are irrelevant at small scales (see §3), so lateral collapse (Heitsch & Hartmann 2008) and star formation can proceed in dense cores (as is indeed observed).

According to our results, what defines whether a given molecular cloud develop a large or a small star formation rate is its particular position and orientation in the Galaxy. It would be interesting to test this proposal with other regions of star-formation. According to Hartmann & Burkert (2007), Orion has a large degree of global collapse. Our results would then suggest that this complex should not be very elongated along the galactocentric radius. Existing observations in the region of the Orion Nebula (Menten et al. 2007) are consistent with this idea, but the distance to young stars spread over a more extended area will have to be measured to test our prediction. Another region where this proposal could be tested is Ophiuchus, where low- and intermediate mass stars are present. Although precise distances would then suggest that this complex should not be filamentary. Again, however, an accurate distance is only known for one part of the complex (NGC 1333 Hirota et al. 2008).

5 CONCLUSIONS

Our analysis of the full gravitational content of the Taurus Molecular Cloud, i.e., considering not only the gravitational energy, but also the tidal contribution from the Galaxy, indicates that TMC must be suffering significant tidal disruption. This suggests that, unlike other clouds (e.g., Orion, see Hartmann & Burkert 2007), TMC is not found in a state of global collapse, explaining thus why it only forms low-mass stars. Small-scale collapse within the complex, on the other hand, is permitted. Such local collapse enhances the formation of molecular gas from H I, and accounts for the rapid formation of stars (Heitsch & Hartmann 2008).

Our result could be tested further if multi-epoch observations similar to those obtained in Taurus by Loinard et al. (2007), Torres et al. (2007, 2008) are performed for different star forming regions exhibiting different efficiencies. Such observations are currently underway.

ACKNOWLEDGMENTS

We thank Paola D’Alessio and Lee Hartmann for a careful reading and useful comments on this manuscript. This work was supported by UNAM-PAPIIT grant numbers 110606, IN111007, and IN119708 to JBP, LL, and BP, respectively, and CONACYT grant numbers J50402-F, 47860, 50720 and 60581 to GCG,LL, BP and BP, respectively. We have made extensive use of the NASA-ADS database. The calculations were performed both on the cluster at CxyA-UNAM acquired with grant 36571-E, and on the cluster Platform 4000 (KanBalam) at DGSCA, UNAM.
