Abstract

\textbf{Aim:} The aim of this study was to investigate the association of hyperoncotic (20\%) human albumin solution (HAS) with outcomes among critically ill patients receiving continuous renal replacement therapy (RRT). \textbf{Methods:} Analysis of the Randomized Evaluation of Normal versus Augmented Level (RENAL) RRT trial data. \textbf{Results:} Of 1,508 patients, 771 (51\%) received albumin. Of these, 345 (45\%) received 4\% HAS only, 155 (20\%) received 20\% HAS only, and 271 (35\%) received both. Patients who received combined 4\% and 20\% HAS were more severely ill, received more days of RENAL trial therapy and required mechanical ventilation for longer. Mean daily fluid balance was $-288$ mL ($-904$ to 261) with 20\% HAS only versus $245$ mL ($-248$ to 1,050) with 4\% HAS only ($p < 0.001$). On Cox proportional hazards regression, 20\% HAS exposure was not associated with greater 90-day mortality (odds ratio 1.12, 95\% confidence interval [CI]: 0.77–1.62; $p = 0.55$) or longer recovery to RRT independence (sub-hazard ratio 1.04, 95\% CI: 0.84–1.30; $p = 0.70$) compared to those who received 4\% HAS only. \textbf{Conclusions:} RENAL trial patients commonly received albumin in varying concentrations. The administration of 20\% HAS was associated with a more negative fluid balance but was not independently associated with increased mortality or RRT dependence when compared to 4\% HAS only.

Introduction

Intravenous (IV) fluids are frequently administered to patients in intensive care units (ICUs) \cite{1, 2}. The selection of such fluids should involve the same considerations as any other medication \cite{3, 4}. A limited number of fluids are...
in common usage however, with varying impacts on patient outcomes [5–9]. Of particular concern is the potential for nephrotoxic effects of some fluid types [5–7, 10–12], with multiple studies demonstrating an association between artificial colloids and worsening acute kidney injury (AKI) [7, 10, 11]. Therefore, when indicated, human albumin solution (HAS) may be the colloid fluid of choice in patients with or at risk of severe AKI. Accordingly, iso-oncotic (4 or 5%) HAS has been used during high-volume resuscitation in critically ill patients and during renal replacement therapy (RRT) to attenuate hypotension and/or facilitate ultrafiltration [13, 14]. In contrast, there is essentially no data on the independent association of hyperoncotic (20%) HAS with clinical outcomes when used during RRT. In particular, iso-oncotic and hyperoncotic HAS are yet to be directly compared in ICU patients receiving RRT for severe AKI [12, 15, 16]. This is despite concern that hyperoncotic solutions may decrease the glomerular filtration rate [14]. Therefore, a direct comparison of iso-oncotic HAS to hyperoncotic HAS is required, to determine whether the formulation of HAS mediates an effect on renal outcomes, as opposed to an effect intrinsic to albumin itself.

The Randomized Evaluation of Normal versus Augmented Level (RENA)l replacement therapy study enrolled a large cohort of critically ill patients treated with continuous RRT for severe AKI in Australia and New Zealand [17]. The study protocol included obtaining detailed data on the administration of HAS. Accordingly, we aimed to use the RENAL database to investigate the association between exposure to hyperoncotic 20% HAS and mortality, recovery to RRT independence, and other clinical outcomes.

### Materials and Methods

The RENAL study was a multicentre, prospective, randomized trial comparing two levels of intensity of continuous RRT in 1,508 adult (>18 years) critically ill patients with AKI, conducted in 35 ICUs in Australia and New Zealand [17, 18]. The Human Research Ethics Committees of the University of Sydney and all participating institutions approved the study (GI-RE-ARF001-40-R). The features of the trial have been previously described [17, 18]. Patients enrolled had AKI requiring RRT and met at least one of the following criteria: oliguria unresponsive to fluid resuscitation, hyperkalaemia, severe academia, blood urea nitrogen >70 mg/dL (>25 mmol/L), creatinine >3.4 mg/dL (>300 μmol/L), or severe organ oedema (clinically significant organ oedema in the setting of acute renal failure, such as pulmonary oedema, as determined by the treating clinician). Patients were treated with continuous veno-venous hemodiafiltration using post-dilution and were randomly assigned to either a higher intensity group (effluent flow rate 40 mL/kg/h) or lower intensity group (effluent flow rate 25 mL/kg/h). The primary study outcome was all-cause mortality within 90 days of randomization (secondary outcomes are outlined in online suppl.; for all online suppl. material, see www.karger.com/doi/10.1159/000517957). Further details are available in the original RENAL study publication [17, 18].

### HAS Therapy

We studied the subgroup of trial patients who received HAS at any stage within the study period. The decision to administer albumin was at the discretion of the treating clinician. The volumes of 4% and/or 20% HAS administered to patients were prospectively collected daily, until death, ICU discharge, or day 28 post-randomization (whichever occurred first). Serum albumin levels were measured daily on morning blood tests for the same period.

### Statistical Analysis

Continuous variables were expressed as mean ± SD or median (interquartile range) and compared using Student’s t test or the Wilcoxon rank-sum test, as appropriate. Categorical variables were expressed as number (percent) and compared using Pearson’s χ² or Fisher’s exact test.

We studied the association between HAS concentration and 90-day mortality using a variety of regression techniques. We performed univariate and multivariable logistic regression adjusting for baseline variables which were clinically or statistically significant, with robust standard errors adjusted for clustering by the ICU site. We created a propensity score model consisting of those variables which were strongly associated with either 90-day mortality or the administration of 20% albumin, employing a backward step-wise elimination process (p < 0.1). We used this propensity score model to estimate the average treatment effect using stabilized inverse probability of treatment weighting (SIPW), as has been utilized in previous observational trials and post hoc analyses [19–22]. Specifically, we defined the propensity score as the probability of a patient being selected for a specific treatment (e.g., 20% albumin) conditional upon available baseline characteristics. Weighting patients by the inverse probability of treatment creates a pseudo-population in which treatment is independent of measured baseline covariates. Stabilized weights reduce the influence of patients with either very low or very high propensity scores [23]. Data were analysed using STATA version 16.0 (Stata, College Station, TX, USA).

We presented time to death within 90 days as Kaplan-Meier curves and compared using Cox proportional hazards regression, with and without SIPW adjustment. We presented results as odds ratios with 95% confidence intervals (95% CIs) and associated p values. The durations of RRT, mechanical ventilation (MV), and ICU and hospital stay were studied using competing risks regression, with death as the competing event, both with and without SIPW adjustment, and are presented as sub-hazard ratios (SHRs) with associated 95% CIs and p values. p values are provided for perspective rather than dichotomous “statistical significance” testing, given all findings are exploratory.

### Results

### Patients

The screening, enrolment, and randomization of patients in the RENAL trial is presented in the original trial.
Table 1. Baseline patient characteristics of recipients of 4 versus 20% versus combined (4 + 20%) albumin

| Characteristic                                      | Albumin 4% only | Albumin 20% only | Combined 4 and 20% | p value |

publication. Of the 1,508 patients included in the RENAL trial, 771 (51%) received HAS. Albumin was administered exclusively in the form of 4% HAS to 345 (45%) patients, as 20% HAS in isolation to 155 (20%) patients, and as a combination to 271 (35%) patients. Several statistically significant differences existed between these groups at baseline (Table 1).

A greater proportion of patients who received 20% HAS had severe organ oedema, while a greater proportion of patients who received 4% HAS had oliguria and severe acidemia. Those who received 20% HAS in combination with 4% HAS had lower serum albumin and creatinine levels at baseline and higher Sequential Organ Failure Assessment cardiovascular and liver scores (Table 1).

Process of Care
Patients who received 4%, 20%, or both received 8, 10, and 17 days of RENAL trial therapy, respectively ($p < 0.001$) (Table 2). The number of patients receiving HAS decreased after day 2 (online suppl. Fig. 1, 2 in Supplementary Material 1).

Among patients who received both 4% and 20% HAS, a greater proportion received 4% HAS on days 1 and 2, though beyond this point the ratio of 4–20% was similar for the ongoing duration of treatment (online suppl. Fig. 1, 2). Patients who received 20% HAS, exclusively or in combination with 4% HAS, had slightly lower plasma albumin throughout the study period. Patients who received both also received substantially more albumin overall (10.5 g [6.5–19.9] per study day) than 4 or 20% HAS in isolation (5.0 g [2.2–10.0] and 5.7 g [3.3–12.5] per study day) ($p < 0.001$).

A greater proportion of patients who received combined 4 and 20% HAS also received fresh frozen plasma, packed red blood cells, platelets, cryoprecipitate and enteral or parental nutrition, and at greater volumes per study day, than those who received either 4 or 20% albumin alone (Table 2).

Variation in the concentration of HAS administered was associated with only small differences in the volume of other IV fluids administered, with an average daily volume of 1.6 L (1.2–2.1 L), 1.4 L (1.0–1.7 L), and 1.6 L (1.2–2.0 L) of crystalloid given to patients administered 4%, 20%, and combined HAS, respectively ($p < 0.001$). However, administration of 20% HAS only resulted in a mean daily fluid balance of minus 288 mL (−904 to 261), while a positive daily fluid balance was recorded with 4% HAS only (245 mL [−248 to 1,050]) or combined HAS (88 mL [−352 to 608]) ($p < 0.001$).

Primary Outcome
Overall, 167 (48%) 4% HAS patients, 80 (52%) 20% HAS patients, and 139 (51%) combined HAS patients died within 90 days of randomization ($p = 0.65$) (Table 3). On SIPW-adjusted Cox proportional hazards analysis, the administration of 20% HAS (either alone or in combination) was not associated with 90-day mortality (odds ratio = 1.12, 95% CI: 0.77–1.62; $p = 0.55$) (Table 4; Fig. 1a).

Renal Secondary Outcomes
Patients who received a combination of 4% and 20% HAS underwent RRT for a longer duration than those who received 4% or 20% HAS alone (9 vs. 4 vs. 6 days, respectively, $p < 0.001$) (Table 3). The proportion of patients who remained dependent on RRT at 28 and 90 days was similar between groups (Table 3). There was no independent association between 20% HAS therapy and recovery to RRT independence after SIPW modelling (SHR = 1.04, 95% CI 0.84–1.30; $p = 0.70$) (Table 4; Fig. 1b).

Tertiary Outcomes
Patients who received combined 4% and 20% HAS were mechanically ventilated for an average of 12 days, compared to 6 days in those who received either 4% or 20% alone ($p < 0.001$) and had an increased dependence on MV at 28 days (14.7 vs. 6.1 vs. 4.6%; $p = 0.007$) (Table 3). On SIPW analysis, the administration of 20% HAS was not independently associated with the duration of MV ($p = 0.37$) (Table 4; Fig. 1c). On multivariate SIPW analysis, the administration of 20% HAS was not associ-

ated with longer duration of ICU stay. However, it was associated with longer duration of hospital stay (SHR = 0.66, 95% CI: 0.49–0.89; p = 0.007) (Table 4).

**Discussion**

**Key Findings**
We studied the administration of hyperoncotic (20%) HAS in patients with severe AKI who were treated with continuous RRT in the RENAL trial. We found that half of RENAL trial patients received albumin therapy, and that among these, half were exposed to 20% HAS either alone or in combination with 4% HAS. A greater proportion of patients who received 20% HAS had severe organ oedema and sepsis. Patients who received only 20% HAS had a more negative mean daily fluid balance. On propensity analysis with SIPW adjustment, the administration of 20% HAS was not associated with mortality, duration of RRT, MV, or ICU length of stay.

---

Relationship with Previous Studies

No previous studies have investigated the association between hyperoncotic HAS and patient outcomes in patients with severe AKI, despite theoretical concerns that hyperoncotic HAS may decrease the glomerular filtration rate [14]. Previous trials such as the SAFE, ALBIOS, and CRISTAL trials compared 4% HAS to 0.9% sodium chloride, 20% HAS to crystalloids, and various colloids to crystalloids, respectively [24–26]. All these studies failed to compare iso-oncotic 4% HAS to hyperoncotic 20% HAS and did not focus on patients with severe kidney injury receiving RRT. This is problematic as patients on RRT may be those most vulnerable to the potentially adverse effects of hyperoncotic HAS. Moreover, both 4% HAS and 20% HAS have mechanisms through which they may worsen AKI. For example, 4% HAS contains a supraphysiological amount of chloride (128 mmol/L) which may cause hyperchloraemia and decrease renal cortical perfusion [5, 6, 16, 27, 28]. Alternatively, 20% HAS is hyperoncotic and thus may reduce glomerular net filtration pressure and therefore reduce GFR [11, 15]. Albumin administration may also promote pro-inflammatory gene expression and increase interstitial fluid volumes with corresponding intracellular dehydration, and these effects may be greatest with the higher concentration 20% HAS [29, 30].

The use of 20% HAS carries potential advantages. It is salt poor and should minimize the fluid volume, sodium, and chloride administered compared to 4% albumin, or indeed any other fluid [31]. These reductions may be of greater clinical significance in patients with severe AKI, who are prone to fluid overload and electrolyte derangement. In this regard, the SWIPE trial randomized 321 patients to fluid resuscitation with either 20% or 4–5% albumin within 48 h of admission to ICU [32]. While the SWIPE trial reported no difference in the rates of new AKI or need for RRT among patients treated with 20% HAS, it only studied 24 patients with AKI at baseline and therefore could not yield robust conclusions regarding its use in such patients. As such, ours is the first study to address this issue in hundreds of patients with severe AKI.

We previously found that HAS is often administered to more severely ill RRT patients and, after adjustment, was associated with prolonged weaning from MV and with prolonged ICU and hospital lengths of stay [22]. Our current analysis of the differential effects of HAS concentration provides a more detailed understanding of the use of albumin in patients receiving RRT for AKI and supports the safety of 20% HAS administration, forming the epidemiological basis for future controlled trials.

Implications of Study Findings

Our findings imply that, in the RENAL trial, the administration of 20% HAS was common. They also imply that oedematous patients and those with sepsis are more likely to be exposed to hyperoncotic albumin during their ICU admission. Moreover, in this context, they imply that 20% HAS therapy was associated with a more negative daily fluid balance and had no independent association with increased risk of mortality or prolongation of RRT use.

Strengths and Limitations

Our study has several strengths. As a post hoc analysis of a large, multicentre randomized trial, it used data that were prospectively collected at baseline and during treatment, and monitored for accuracy. This provided high-quality, detailed and novel data regarding the administration of hyperoncotic HAS to patients requiring RRT for AKI and their subsequent outcomes. To our knowledge, this represents the largest study to provide a direct comparison of hyperoncotic to iso-oncotic albumin in critically ill patients, and the first to do so specifically in a cohort of patients with severe AKI treated with RRT. Final-

Table 4. Patient outcomes at day 90, unadjusted (n = 772) and inverse probability of treatment weighted (n = 662), for administration of any 20% versus only 4% albumin

| Mortality | OR (95% CI) | p value |

ly, we have extensively adjusted for baseline confounding in the association between 20% HAS exposure and clinical outcomes.

We acknowledge several limitations. Our study is not a randomized controlled trial. Therefore, we can only describe associations after adjustment for measured relevant confounders. Thus, any inferences of causality are limited by the risk of unmeasured confounding. We are also unable to determine the mechanism through which associations arise. For example, the administration of hyperoncotic albumin was associated with a more negative daily fluid balance, which may reflect that these patients were at a different stage of their illness and resuscitation, or may have been because a greater proportion of these patients had severe organ oedema at baseline. Similarly, patients who were administered both 4% and 20% albumin received more packed red blood cells, which may have been in response to a haemodilutional effect of HAS or may reflect the generally greater severity of illness of these patients. Furthermore, we are unable to identify a mechanism through which hyperoncotic albumin may cause a longer hospital length of stay without altering ICU length of stay or mortality. This likely reflects unmeasured confounding, whereby clinicians chose to administer hyperoncotic albumin to more severely unwell patients who were at a higher risk of prolonged hospital stay.

The RENAL trial was conducted in Australia and New Zealand, where albumin is the colloid fluid of choice.
Therefore, albumin may have been administered more liberally than elsewhere. This may limit the generalizability of our findings to other contexts. However, such increased use provided our study with greater statistical power because of the number of patients exposed to hyperoncotic albumin solution. The RENAL trial was conducted from 2005 to 2008 and IV fluid practices may have changed since that time. However, no data exist to confirm or refute this possibility. Unfortunately, we do not have data regarding fluid administration prior to randomization in the RENAL trial, and this is a potential confounder which may have influenced the decisions of treating clinicians. As all patients received RRT throughout the RENAL study, detailed data regarding their renal function was not available, as serum creatinine only represented the intensity of RRT. However, we used the time to cessation of RRT as an imperfect but clinically relevant patient outcome and found no association between hyperoncotic HAS therapy and the rate of recovery to RRT independence.

Conclusions

HAS was administered to half of the patients treated with continuous RRT in the RENAL trial, with half of such patients being exposed to hyperoncotic (20%) albumin. Such 20% HAS therapy was associated with a more negative mean fluid balance and, after adjustment, was not independently associated with increased mortality or decreased rate of recovery to RRT independence. Our results support that in high-risk critically ill patients receiving RRT, 20% HAS therapy is safe, and justify the conduct of further investigations of such therapy in this context.

Statement of Ethics

The Human Research Ethics Committees of the University of Sydney and all participating institutions approved the study (GIRE-AF001-40-R). Written informed consent was obtained from patients or their responsible surrogate.

Conflict of Interest Statement

Professor Rinaldo Bellomo received consulting fees as an advisor for Gambro and consulted for Gambro, Biosite, Abbott, and Philips. Dr. Gallagher received honoraria/speaking fees from Roche. The remaining authors have no conflicts of interest to declare.

Funding Sources

The RENAL study was supported by grants from the National Health and Medical Research Council (NHMRC) of Australia (grant no. 352550) and Health Research Council (HRC) of New Zealand (grant no. 06–357). The study sponsors had no role in study design; collection, analysis, and interpretation of data; writing the report; or the decision to submit the report for publication. The George Institute has received research funding from Servier, Novartis, Eisai, Merck, Sharp & Dohme, Pfizer Australia, Fresenius Kabi Deutschland GmbH, and Sanofi Aventis. The Randomized Evaluation of Normal versus Augmented Level (RENAL) Replacement Therapy Study is a collaboration of the Australian and New Zealand Intensive Care Society Clinical Trials Group (ANZICS CTG) and the George Institute for International Health.
