ABSTRACT
We present a kinematical study of 29 spiral galaxies included in the Spitzer Survey of Stellar Structure in Galaxies, using Hα Fabry-Perot data obtained with the Galaxy Hα Fabry-Perot System instrument at the William Herschel Telescope in La Palma, complemented with images in the R band and in Hα. The primary goal is to study the evolution and properties of the main structural components of galaxies through the kinematical analysis of the FP data, complemented with studies of morphology, star formation and mass distribution. In this paper we describe how the FP data have been obtained, processed and analysed. We present the resulting moment maps, rotation curves, velocity model maps and residual maps. Images are available in FITS format through the NASA/IPAC Extragalactic Database and the Centre de Données Stellaires. With these data products we study the non-circular motions, in particular those found along the bars and spiral arms. The data indicate that the amplitude of the non-circular motions created by the bar does not correlate with the bar strength indicators. The amplitude of those non-circular motions in the spiral arms does not correlate with either arm class or star formation rate along the spiral arms. This implies that the presence and the magnitude of the streaming motions in the arms is a local phenomenon.

Key words: galaxies: kinematics and dynamics - galaxies: spiral - galaxies: star formation.

1 INTRODUCTION

Galaxies are the basic building blocks of the Universe and understanding their nature, formation and evolution is crucial to many areas of current astrophysical research. Con-
cretely, nearby galaxies are the vivid result of the evolution of the Universe, they contain the footprints of the evolution processes that have led to the present status of the galaxies. To better understand the evolutionary history of the Universe, it is necessary to study the structure and dynamics of current galaxies. By studying the kinematics of galaxies we can trace the motions of both their baryonic (gas and stars) and dark matter.

Radial velocity measurements have been traditionally performed with radio observations, mainly using the 21-cm H I line. Tracing this neutral hydrogen line lets us study most of the gas content of the galaxy, usually traced out to three or four times beyond the visible disc. Rots (1975), Bosma (1978), van der Hulst (1979), Bosma (1981); Gottesman (1982) and others demonstrated the power of rotation curves in deriving the total mass distribution of disc galaxies. The drawback with these H I radio observations was the poor angular resolution. The highest angular resolution (∼ 6″) 21-cm H I surveys of nearby galaxies to date have been carried out by the HI Nearby Galaxy Survey (THINGS; Walter et al. 2008), using the Very Large Array (VLA) of the NRAO. CO radio observations have also been used traditionally to trace the molecular gas. Nowadays, CO observations provide high angular resolution (comparable to optical), and also high spectral resolution (from one to several km s\(^{-1}\)), but in very small fields.

Optical (Hα, NII) observations yield high arcsecond angular resolution data. Hα is often the brightest emission line in the visible wavelength range due to the cosmic abundance of hydrogen. In spiral galaxies, this line traces primarily the ionized gas in H I regions around young massive stars. In the 20th century, most of the optical observations were based on long-slit spectroscopy. Long-slit observations have been traditionally used to deduce the rotation curves of galaxies (e.g., Rubin, Ford & Thonnard 1980; Rubin et al. 1982; Rubin & Ford 1984; Mathewson, Ford & Buchhorn 1992; Persic & Salucci 1995; Mathewson & Ford 1996; Courteau 1997; Dale et al. 1997, 1998, 1999).

However, 3D spectroscopy [IFU, Fabry-Perot (FP), multi long-slit spectroscopy] of galaxies is one of the best methods to obtain detailed information on the kinematics of galaxies. Velocity maps derived using 3D spectroscopy reproduce the complete velocity field, contrary to longslit spectra. Hα observations using FP instruments have been used for some 40 years now (Tully 1974; Deharveng & Pellet 1975; Dubout et al. 1979) or de Vaucouleurs & Pence (1980) and have been designed to derive velocity fields of nearby galaxies (e.g., Atherton et al. 1982) or Boulesteix et al. 1984), and to create high signal-to-noise ratio (S/N) rotation curves for many spiral galaxies (e.g., Marcelin, Boulesteix & Georgelin 1985; Bonnaire et al. 1988; Pence, Taylor & Atherton 1990; Corradi & Capaccioli 1991; Amram et al. 1992; Cecil, Wilson & Tully 1992; Amram et al., 1994; Sicotte, Carignan & Dufour 1996; Ryder et al. 1998; Jimenez-Vicente et al. 1999; Knapen et al. 2000 and many more).

Chemin et al. (2006) presented an Hα FP survey of Virgo cluster galaxies. Daigle et al. (2006a) also presented an Hα FP survey complementary to the Spitzer Infrared Nearby Galaxies Survey (SINGS; Kennicutt et al. 2003). One of the largest and most important FP surveys in Hα is the Gassendi Hα survey of S Pirals (GHASP; Garrido et al. 2002). The GHASP survey consists of a sample of 203 spiral and irregular galaxies that have been observed with a sampling of about 16 km s\(^{-1}\) in velocity and an average 3 arcsec in angular resolution (see Epinat, Amram & Marcellin 2008). GHASP VII hereafter, for a complete list of data and resolutions). Hα FP spectrographs are nowadays being used for studying the kinematics of several kinds of galaxies, e.g., bulgeless galaxies (Neumayer et al. 2011), starburst galaxies (Blasco-Herrera et al. 2013), or interacting galaxies in compact dwarfs (Torres-Flores et al. 2014).

One of the newest FP spectrographs is the Galaxy Hα Fabry-Perot System (GHaFaS). It is a visiting instrument on the William Herschel Telescope (WHT) in La Palma. The GHaFaS instrument has been operative since 2007 (Fathi et al. 2007), and has been used to study pattern speeds of bars and spiral arms (Fathi et al. 2009), to analyse the kinematics of planetary nebulae (Santander-García et al. 2010), and the gas flows (Font et al. 2011b), star formation and the kinematics of interacting galaxies (Zaragoza-Cardiel et al. 2013, 2014) and starburst galaxies (Blasco-Herrera et al. 2013). It has also been used to study the resonance radii and interlocking resonance patterns in galaxy discs (Font et al. 2011a, 2013a).

We have designed an observing programme to obtain FP data of 29 spiral galaxies with the GHaFaS instrument, as part of the ancillary data of the Spitzer Survey of Stellar Structure in Galaxies (S^4G; Sheth et al. 2010). The S^4G survey has obtained 3.6 and 4.5 μm images of 2352 nearby galaxies using the Infrared Array Camera (IRAC; Fazio et al. 2004). The sample is composed by galaxies that fulfill these requirements: d < 40 Mpc, m_b < 15.5, D_25 > 1 arcmin, and includes galaxies selected using values from HyperLeda (Paturel et al. 2003), with a radial velocity v_{radio} < 3000 km s\(^{-1}\) and galactic latitude |b| > 30°. The cornerstone of the S^4G survey is the quantitative analysis of photometric parameters, enabling a variety of studies on secular evolution, outer disc and halo formation, galaxy morphology, etc. The data have been made public\(^1\). The first papers resulting from S^4G survey have been summarised in Holwerda et al. (2014).

The combination of the S^4G mid-IR images with these complementary FP data at high resolution will allow us to tackle the scientific goals of this study, summarized as followings:

(i) Perform a detailed study of the kinematical interplay between the interstellar medium and regions of star formation, dust, or other activity.

(ii) Use the kinematics as a probe of the secular evolution, as manifested in the structural components such as bars, spiral arms, rings, lenses, etc.

(iii) Exploit the high angular resolution of the kinematic data to study the inner parts of rotation curves, and relate the galaxy kinematics to the mass distribution and specific observed properties, as well as probing the coupling between the stellar density and the gravitational potential in the inner parts of the galaxies.

(iv) Study possible deviations of the rotation curve that are caused by lopsidedness or asymmetries in the outer parts of the disc, which would help to pin down the interplay between dark matter (DM) and stars.

\(^1\) [http://irsa.ipac.caltech.edu/data/SPITZER/S4G/]
(v) Explore the outer disc kinematics, to establish whether disc is generally cold and thus to constrain the halo properties.

This data paper is the second of a series, and presents the complete set of FP and narrow-band imaging data for the 29 galaxies in our kinematical study. In Paper I (Erroz-Ferrer et al. 2012), we illustrated the data and methods, and discussed the kind of results that the main survey will provide through a detailed analysis of NGC 864, an archetypal barred spiral galaxy. In Paper III (Erroz-Ferrer et al.; in prep.) we will present the results from a study of the inner part of the rotation curves of the galaxies of the sample; and Paper IV (Leaman et al.; in prep) will study the outer-most parts of the discs of the galaxies of the sample and the relationship between their kinematics and DM.

This paper is organized as follows: Section 2 gives a description of the sample selection, and Section 3 describes the observations. Section 4 describes the data reduction and results. The derived rotation curves and non-circular motions maps are presented in Sections 5.1 and 5.2 respectively. These results are discussed in Section 5.4 and Section 6 presents our conclusions.

2 TARGET SELECTION

The galaxies in our survey satisfy the following requirements: first of all, the declination should be higher than $-10^\circ$ so that the altitude in the sky could be enough at the time of the observation in La Palma, and only galaxies with inclinations between $0^\circ$ and $70^\circ$ were selected.

According to the instrument specifications, the galaxy should fit well in the GHaFaS FOV of 3.4 $\times$ 3.4 arcmin. Therefore, galaxies with diameters between 2 and 3.4 arcmin were selected. Secondly, the range in velocity of the galaxy should not be higher than the free spectral range (FSR) of the instrument (see Sect. 3 for details), although we did not have this ancillary information for all the galaxies. Furthermore, the data reduction processes require that the galaxy should have at least three bright point sources in the field, i.e. three stars or two stars and the nucleus.

The observed sample was selected at the time of the observations, looking at the visibility on the sky, but also requiring a spread in morphological type, bar presence and finally, the availability of ancillary data (interferometric CO, HI, ultraviolet or Spitzer mid-IR).

The final sample consists of 29 galaxies. For the morphological classification, we have followed the up-to-date Mid-IR Classifications for S$^4$G Galaxies in the Comprehensive de Vaucouleurs revised Hubble-Sandage System (CVRHS, Buita et al. 2015). The morphological classification also includes bar presence (9 SA galaxies, 12 SAB galaxies and 7 SB galaxies). In Fig. 1, we present the morphological classification as a histogram. The general properties of the galaxies in the sample are presented in Table I. As noted in the footnote of Table I the galaxy NGC 7241 is nearly edge-on. The galaxy has an unusual interacting companion in the line of sight, its photometric inclination is biased much lower and therefore we do not include it in the analysis part of this paper. A detailed analysis of it is presented separately in Leaman et al. (in prep.).

3 OBSERVATIONS

The Fabry-Perot observations were carried out using the GHaFaS instrument mounted on the 4.2-m WHT in La Palma. The observations were done during 24 nights between September 2010 and March 2013.

The instrument is a Fabry-Perot interferometer that provides high spectral resolution and seeing-limited angular resolution data, within a 3′×3′ FOV. The instrument comprises a focal reducer, a filter wheel, a Fabry-Perot etalon, an image photon-counting system (IPCS), and a calibration lamp (neon source). The etalon used has an interference order of 765 and a FSR of 391.9 kms$^{-1}$ (8.6 Å). Each observational cycle consists of 48 steps (named channels) through the etalon for 10 seconds each. The number of cycles depends on the galaxy magnitude, but usually amounts to some 3 hours (corresponding to 22 cycles). However, due to weather and instrumentation problems, not all the galaxies were observed for the same length of time (all the information about the observations is collected in Table II). The high spectral resolution mode was used, achieving a velocity sampling of ~8 km s$^{-1}$ with a pixel scale of 0′′.2 in 1K×1K pixel images. In Table II we summarize the instrumental setup used in the observations.

To perform flux calibration, Hα narrow-band images were observed together with the Fabry-Perot observations, using the Auxiliary port CAMera (ACAM), permanently mounted at a folded-Cassegrain focus of the WHT (Bennett, Dee & Agocs 2008). The FOV in imaging mode is 8 arcmin, with a pixel size of 0.25 arcsec. The R-band images were taken using a Bessel filter with central wavelength 6500Å and full width half maximum (FWHM) of 1360Å, and with a Sloan 6228/1322 filter (central wavelength/FWHM, in Å). We used four different Hα filters depending on the galaxy’s redshift (6577/23, 6589/24, 6613/24 and 6631/17; central wavelength/FWHM, in Å). The exposure times per galaxy were $3\times20$ seconds for the R-band images and $3\times100$ seconds for the Hα images. The typical seeing was around 1 arcsec, ranging from 0′′.6 to 1′′.6.

Table 1. General properties of the galaxies in the sample. Notes. (1) Updated morphological classifications from the CVRHS, where “double stage” galaxies are allowed (i.e., large-scale S0 or S0/a galaxies with smaller-scale inner spirals) (2) Adopted values of the distances, calculated after applying the Virgo, GA and Shapley corrections, with $H_0 = 73 \pm 5$ km s$^{-1}$ Mpc$^{-1}$ from the NASA/IPAC Extragalactic Database (NED). The uncertainties in the distance measurements have been adopted as 20 per cent of the value. (3) $B$ magnitude from The Third Reference Catalogue of Bright Galaxies (RC3; de Vaucouleurs et al. 1991). (4) Absolute $B$ magnitude measured using the distance and $m_B$ of columns III and IV. (5) Absolute 3.6 $\mu$m magnitude measured using the distance of column III and asymptotic magnitude at 3.6 $\mu$m from the ellipse fitting to the 3.6 $\mu$m S$^4$G images (Muñoz-Mateos et al. in prep). (†) NGC 7241 is nearly edge on, but due to a line of sight companion galaxy, the photometric inclination is biased much lower and should not be considered representative.

4 DATA REDUCTION

4.1 H$\alpha$ imaging: ACAM

The ACAM images were reduced initially using IRAF. First, bias and flat corrections were made. Then, the sky was subtracted before and after the combination of the exposures. The images were astrometrically calibrated using KOORDS in KAPPA first, setting a preliminary astrometry using the DSS images as a reference. Afterwards, we used GAIA in STARLINK to improve the astrometry with the GSC-2 catalogue at ESO. The next step was aligning the $R$-band and H$\alpha$ images for each galaxy, subtracting the continuum using the procedures outlined in Knapen et al. (2004) and Sánchez-Gallego et al. (2012). Finally, the continuum-subtracted H$\alpha$ images were flux calibrated using spectrophotometric standard stars observed at the time of the observations.

The resulting continuum-subtracted image of NGC 2748 is presented in panel f) of Fig. 2. The images of the other galaxies in the sample are presented in Appendix A.

4.2 Fabry-Perot: GH$\alpha$FaS

The basic custom reduction of GH$\alpha$FaS data cubes has been explained in previous papers in the literature (e.g., Hernández et al. 2008 or Blasco-Herrera et al. 2010), and was introduced in Paper I. The data of all the galaxies have been reduced following these steps: de-rotation, phase-correction, combination and wavelength calibration, astrometry correction, spatial smoothing, continuum subtraction, removing sky lines, flux calibration and creation of the moment maps.

4.2.1 De-rotation, phase-correction, combination and wavelength calibration

There is no suitable de-rotator at the Nasmyth focus of the WHT. Therefore, the first step is to de-rotate the data cubes. To do this, we followed Blasco-Herrera et al. (2010). At least two point sources in all the planes are selected (ideally stars), and selected throughout the cubes. After that, each plane of the subsequent cubes is de-rotated to the same position.

Due to the nature of the FP data, any 2D spatial transformation (rotation or translation) has to be done also in the third dimension (the spectral dimension), and therefore de-rotation must be done simultaneously with the phase calibration. The wavelength calibration is also performed at this point. Lamp exposures were taken between galaxy observations and are used to calibrate in wavelength (see Carignan et al. 2008). The integration of all the cubes from the various cycles is performed after the de-rotation and phase calibration. The result is one 48-channel cube, phase-corrected and calibrated in wavelength.
4.2.2 Astrometry calibration

The data are placed on an astrometrically correct spatial grid by comparing the positions of stars in the ACAM Hα images. The astrometric calibration of the ACAM images is explained in Sect. 4.1.

4.2.3 Spatial smoothing

The instrument delivers data cubes with a spatial scale of 0′′.2/pix, and therefore the spatial resolution is limited by the seeing. If the de-rotation process is not correctly performed, the spatial resolution might change (i.e., the addition of misaligned cubes would result in a blurred cube, the PSF of the point source rises and therefore the seeing increases). Thus, the de-rotation output has been carefully checked in order to minimise changes in the resolution.

We applied a 2D Gaussian smoothing kernel with a FWHM of 3 pixels to the data in order to improve the signal-to-noise ratio (S/N) without degrading the angular resolution too much. To apply this Gaussian kernel, we have used the IDL task filter_image.pro.

4.2.4 Continuum subtraction

The resulting de-rotated, phase-corrected and wavelength-calibrated data cube is then imported into gipsy (Groningen Image Processing System; van der Hulst et al. 1992). The continuum was subtracted using conrem of gipsy, which estimates the continuum level from line-free frames. To determine the channels free of line emission, we visually check the images and also the spectra, after additional smoothing.

For NGC 2748, NGC 5678 and NGC 6070, the velocity amplitude is equal or larger than the FSR and there are no channels free of line emission. The Hα line falls into the next interference order and reappears in the first or last channels (what we call “peak intrusion”). Those channels containing emission from a peak intrusion are copied after or before the first or last channel, where they should really be, increasing the number of channels per cube. Then, we divided the cube spatially in two parts (roughly corresponding to the areas where emission from the receding and approaching halves is seen). The channels free of emission were identified separately for each sub-cube, and the continuum was calculated and subtracted separately in each sub-cube. After the continuum subtraction, the two cutouts have been combined again.

4.2.5 Sky line removal

Stationary secondary peaks sometimes appear in the data cubes, usually located in three channels, peaking in the middle one and with a circular light gradient along the image (more light in the centre and gradually less light as leaving the centre). These are OH sky emission lines due to airglow, peaking near the following velocities/wavelengths: 690 km s\(^{-1}\)/6577.3 Å (present in NGC 2500, NGC 2541, NGC 4389 and NGC 6207), 1080 km s\(^{-1}\)/6586.5 Å (NGC 428, NGC 1073, NGC 3403, NGC 4151, NGC 4639 and NGC 5112) and 1480 km s\(^{-1}\)/6596.7 Å (NGC 4498, NGC 5334 and NGC 6412). To remove this contribution, we have dealt with the channels as if they were images to correct for flat fielding. With FLAT of gipsy, we fitted a polynomial to the background, eliminated the gradient across the affected planes and flattened the background.

4.2.6 Flux calibration

We calibrate the Fabry-Perot data by using calibrated narrow-band Hα imaging. As explained in Sect. 3 the kinematic data have been observed together with ACAM data. The procedure was explained in Paper I: fluxes from selected H\(\alpha\) regions in both ACAM and H\(\alpha\) FP data are compared, and fitted to a linear relationship. As a consequence, the zeroth moment maps (intensity maps, see the following section) are flux-calibrated. GHASP VII uses a different method to flux-calibrate their FP observations. Instead of carrying out their own observations, they compare the integrated H\(\alpha\) flux of their galaxies to that of the narrow-band observations in James et al. (2004). Although our method requires more observing time at the WHT, it is more accurate as both FP and narrow-band imaging observations are carried out under the same atmospheric conditions and airmass.

4.2.7 Moment maps

To create the moment maps we have used the MOMENTS2 task of gipsy, which performs an intensity weighted mean of the physical coordinates along the profile.

We imposed the condition that the line emission had to be present in at least three adjacent channels and at a level above a certain noise level \(\sigma\) in the profiles. To do that, we determined \(\sigma\) for each galaxy using \texttt{stat} in gipsy, and we created the sets of moment maps with emission above 5\(\sigma\). Also, we imposed the condition that secondary peaks are not taken into account (although secondary peaks are assumed not to be present after the previous reduction processes).

Subsequently, from the smoothed and continuum-subtracted cube we computed the moment maps for each galaxy, specifically the moment maps of order zero (intensity map), order one (velocity map along the line of sight) and order two (velocity dispersion maps). The velocity dispersion maps will be used in Paper III, and they will be corrected for instrumental, thermal and natural line broadening. The natural width has a value of 3 km s\(^{-1}\) (O’dell & Townsley 1985). The thermal width corresponds to 9.1 km s\(^{-1}\), assuming a temperature of 10\(^4\) K (Osterbrock & Ferland 2006). The instrumental width for each galaxy was obtained from the data cube taken with the calibration lamp, following the procedures in ?, and is 8.3 km s\(^{-1}\).

After creating the moment maps, the stars and central regions may leave a residual (i.e., the continuum may not be properly determined and removed), and therefore the outputs from MOMENTS2 need to be masked. Specifically, for the AGN hosts NGC 4151 and NGC 4639, the central emission saturated the detector and in consequence the continuum subtraction could not be removed properly, leaving a residual that had to be masked out. Also, we have masked the central regions in NGC 4324, NGC 5740 and NGC 5921, 2 https://www.astro.rug.nl/~gipsy/tsk/moments.dcl
since the signal there is due to continuum emission (i.e., no line emission is detected).

For each galaxy, we created a six-plots figure, presenting the resulting velocity maps and the outputs from the analysis. In Fig. 2, we present the resulting moment maps for NGC 2748 in the top images. The figures for the other galaxies in the sample are collected in Appendix A.

5 DATA ANALYSIS

5.1 Rotation curves

To understand the circular motions within a galaxy, rotation curves have been used widely. Here, we study the rotation of the gas, and in particular, the gas from the H II regions that have been heated by massive, young stars. To extract the rotation curve from the velocity map we have used the ROTCUR task in GIPSY. This procedure is based on the tilted-ring method described by Beger (1989), where each ring can be defined by the parameters: inclination (i), position angle (PA), centre (x₀ and y₀) and systemic velocity (vsys). If we assume that the radial and vertical velocities are negligible, the observed velocity can be expressed as vobs(R, θ, i) = vsys + vrot(R, θ) cos θ sin i, where θ is the azimuthal angle in the plane of the galaxy and depends on i, PA, x₀ and y₀.

It is not easy to determine the rotation curve parameters, as deviations from rotational motions can be present inside the galaxies, some of our galaxies are not much inclined, and most of the velocity fields are sparsely sampled. However, we have proceeded to ensure that we are obtaining the true rotation curve while minimising possible errors. In order to determine the starting values (i.e., initial conditions) of i, PA, x₀, y₀ and vsys, our first step was to search the literature (RC3, de Vaucouleurs et al. 1991; HyperLeda, Paturel et al. 2003; GHASP VII; and Muñoz-Mateos et al. in prep). We then derived position-velocity diagrams (PV diagrams) along the kinematic major axis of the galaxies in order to see the rotation in the spatial direction (presented as supplementary material in the Appendix C).

Then, we proceeded with R0T0CUR as usual: (1) All parameters were left free. (2) To obtain the position of the galaxy centre, the PA, inclination, and systemic velocities were fixed, and the centre values were free. In the majority of the cases, the fits were unsatisfactory due to the patchiness of the data. In the galaxies whose centre is represented by a bright point source (nucleus), we adopted that as the dynamical centre. In the cases where the fits were unsatisfactory and the centre is not presented with a point source, we adopted the value from NED. In any case, the centre position angle (PA), and inclination were fixed in order to fit the systemic velocity. (3) The centre position, PA, and inclination were fixed in order to fit the systemic velocity. (4) The PA and inclination were then left free with all other parameters fixed. (5) Finally, the rotation curve was obtained by fixing all parameters except the rotation velocity.

In all the steps, we avoided the sector under 30° from the minor axis and a [cos(θ)] weight was applied to the line-of-sight velocities during the fittings. The objective was to minimize the errors caused by the points close to the minor axis, where important projections effects occur and where the circular velocity term is fitted with difficulty [cos(θ) → 0]. To determine (fix) one parameter, we forced the mean of the values of the rings to satisfy the following conditions, based on our experience and linked to the resolution of our data: (i) The number of points in each ring should be greater than a sufficient number, usually 20-50 (20 is the minimum number of points in a region with the size of our angular resolution, which is ∼1 arcsec). (ii) The difference between the average of all the values from all the rings and the value in the given ring should not be more than 15 km s⁻¹ for vsys and 15° for the PA and i (15 km s⁻¹ is our velocity resolution, twice the velocity sampling). (iii) The uncertainty coming from the free values in the fit (i.e., vsys and the rotational velocity in step 2) should not be more than 10 km s⁻¹ for the velocities and 10° for the PA and i. Usually, these conditions coincided to pick out those cases where the fit was not satisfactory, and the corresponding values were not taken into account in the average. All the rotation curves have been computed taking into account both approaching and receding sides, and the error bars are the dispersion of the rotation velocities computed for all the pixels in each elliptical ring.

To check that the fixed values represent the true rotation, we looked at the residual map (see the following section) to search for systematic errors. For example, if the residual map tends to have negative values, it is because the fixed systemic velocity is too large. Other systematic effects that appear in the residual map when one parameter is badly selected are presented in Fig. 8 of Warner, Wright & Baldwin (1974). Also, we superimposed on the PV diagrams along the major axis the deprojected rotation curve at the corresponding angle, confirming that the derived rotation curves are correct (see Appendix C).

We have created two types of rotation curves: a high-resolution curve (with a separation of 1” between points) and a low-resolution curve (with a separation of 5”). The high resolution curve traces better the behaviour of the curve and the small-scale features of the galaxy, although it is noisier as there are fewer pixels taken into account in the fit for each radial point.

The parameters (i, PA and vsys) resulting from the low-resolution fit are presented in Table 4. For NGC 2748, the high-resolution rotation curve is presented in Fig. 3. The resulting high-resolution rotation curves for all the sample galaxies are presented in the Appendix B.

5.2 Non-circular motions and residual velocity fields

With the rotation curves we explore the circular rotation of the sample galaxies. However, there can be deviations from these circular motions provoked by dynamical features of the galaxy, such as the influence of the potential of the bar, past interactions with a companion or streaming motions across the spiral arms. To understand the influence of these features on the galaxy kinematics, we want to study these deviations from rotation, in other words, the non-circular motions.

Following the technique described in Paper I, the first step is to create a velocity model map that reflects the ro-
NGC 2748

Figure 2. Results from the analysis of the Fabry-Perot data cubes of the spiral galaxy NGC 2748. a) Hα intensity map. b) Velocity map. c) Velocity dispersion map. d) Velocity model map. e) Non-circular motions map. f) Hα narrow-band image from ACAM. In the images, North is up and East to the left. All the images have the same scale. Similar panels for all the sample galaxies are presented in App. A.

Figure 3. High-resolution rotation curve derived from the 5-σ velocity map of NGC 2748. Rotation curves for all the sample galaxies are presented in the Appendix B.

Our procedure consists of studying separately those parts of galaxies most directly affected by the spiral density waves (spiral arms), those affected by the potential of the bar (bar region), and those affected by both potentials: the start of the spiral arms close to the bar (start-of-arms-region, SAR hereafter). We have defined these three regions (arms, bars and SAR) using images from NED (mainly SDSS false-colour images by Baillard et al. 2011), 3.6 μm 24G images (using the output from the 2D decompositions of the 3.6 μm images by Salo et al. 2015, to better constrain the bars) and our Hα ACAM images. Thus, we are not biased
by a star formation-based classification when defining the regions, because there are barred galaxies that show the bar in the mid-IR but not in Hα.

Firstly, based partly on the SDSS images but mainly on the IR images, we have defined the region where the stellar bar is, also taking into account the bar position angle and bar length (see Sect. 5.5). Secondly, we have identified by eye those regions that are between the spiral arms and the bar, and which might be influenced by both (SARs). Finally, we have identified the spiral arms by looking at the intensity contours on the SDSS and 3.6 μm images, drawing by eye their extension on the IR images. In the more flocculent spiral arms, it is not easy to identify the extent of the spiral arms, so everything except for the bar and SAR is assumed to be spiral arms. The three regions have been defined astrometrically with irregular shapes, and can be identified at all used wavelengths. In Fig. D1, we present the 3.6 μm S^4G images of the barred galaxies with overlaid in red and yellow, a schematic representation of the bar region and the SAR for each barred galaxy. For completeness, we have added NGC 5678, a galaxy which may have a bar

Table 4. Results. Column I) Galaxy name. Column II) Systemic velocity from optical observations (HyperLEDA). Column III) Systemic velocity derived from our FP data. Columns IV and VI) Disc inclination and PA obtained from the 25.5 mag/arcsec^2 isophote from the ellipse fitting to the S^4G 3.6 μm image (Muñoz-Mateos et al. in prep). Columns V and VII) The same as columns IV and VI but derived from our FP data. Column VIII) Maximum velocity derived from the rotation curves. Column IX) Quality flag for the maximum velocity: reached in our data (1), probably reached (2), probably not reached (3), not reached (4). Notes: (1) PA of the major axis is defined as the angle, taken in anti-clockwise direction between the north direction on the sky and the kinematical major axis of the galaxy, defined from 0° to 180°. (2) For NGC 1073, 180° have been added to PA_{4.6μm} for a direct comparison with PA_{Hα}. (3) The AGN contribution has been excluded from the measurements.

Ha kinematics of S^4G spiral galaxies-II. Data description and non-circular motions

To quantify the non-circular motions, we have studied the cumulative distribution function (CDF) of the pixel values in the residual images. We have adopted the value of the 95% of the distribution of the residual velocities (in absolute value) as a representative value of the overall non-circular motion within that region. With this method, we avoid introducing possible caveats: if we had used a histogram, the bin size would have changed the adopted value for the residual velocity; and if we had defined regions of certain physical scale, the size of the region would matter. Another advantage of the method is that the correlations and trends would not change if we choose 50, 70 or 95%, as we represent the distribution of all the values. The uncertainties were estimated via a Monte Carlo simulation of the effect of adding random noise to the velocity residuals, the former following a Gaussian distribution with sigma equal to the spectral sampling. In Fig. 4, we present the statistical distribution of the residual velocities of the arm region in NGC 2748. The adopted value for the residual velocities there is 23.2 ± 1.8 km s\(^{-1}\); which corresponds to the representative value in
the residual map of NGC 2748 (panel c in Fig. 2). The computed values for the non-circular motions in the bar, SAR and spiral arms are presented in Table 5.

For completeness, we have normalised the residual velocities. To do so, we have computed the corresponding circular velocity at a radius equal to the bar length, to the extent of the SAR, and to the last measured point (assuming that the spiral arms end there), following the universal rotation curve by Persic & Salucci (1991). This method includes several uncertainties, such as assuming that the circular velocity across the complete region is equal to that at the last radial point, or that the region is circular with a radius the extent of the structure (bar, SAR or arms). Note that the residual velocities have been deprojected.

5.3 Structural parameters

To understand the nature of the non-circular motions within the regions of the galaxies, we study them in conjunction with some of the structural parameters that have been derived for the galaxies of our sample.

The bar strength is quantified by the torque parameter $Q_b$, which describes the maximum amplitude of tangential force normalised by axisymmetric radial force (Combes & Sanders 1981; Buta & Block 2001). $Q_b$ values have been measured from the torque maps derived from the 3.6 $\mu$m S4G images (for a description of the method see Salo et al. 2010 and Laurikainen & Salo 2002), and will be published in a compilation of bar strengths for the S4G sample (S. Díaz-García et al., in prep).

The parameter $Q_b$ is defined so that $Q_b$ decreases with the axisymmetric radial force, hence the presence of the bulge is implicitly present in $Q_b$. Due to the bulge influence, $Q_b$ is not the best parameter to show the strength of the bar on the gas kinematics. However, we will use those $Q_b$ values as they are the only ones that measure the bar strength that have been derived from the S4G images. We have also studied the bulge-to-total ratio ($B/T$). The values from $B/T$ have been derived from 2D decompositions of the 3.6 $\mu$m images (Salo et al. 2015). We list the $Q_b$ and $B/T$ values for the galaxies of our sample in Table 5.

The bar lengths have been measured from the torque maps (Díaz-García et al., in prep.). The bar lengths are deprojected units, measured using the method explained in Salo et al. (2010), except when the fits do not have trustworthy quality, in which the bar lengths are measured visually (Herrera-Endoqui et al., in prep.).

We have also studied the spiral arm class, as a parameter that is related to the spiral arm strength. We have obtained the arm class classifications carried out by D. Elmegreen and presented in the CVRHS, where F means flocculent, M denotes multi-armed and G grand design. Note that NGC 4324 has not been presented in the table as it does not have an arm class classification. The values for the arm classification are in Table 5.

5.4 Star formation rates

The H$\alpha$ line traces the emission from massive young stars. The advantages of this recombination line are that it traces very recent SF (timescales ~6–8 Myr), and that it has lower sensitivity to dust attenuation than the UV (although not negligible; Cardelli, Clayton & Mathis 1989). Thus, we can exploit the H$\alpha$ imaging and relate the star formation to the galaxy’s kinematics. We derive the star formation rates (SFRs) derived from the H$\alpha$ luminosity ($L_{H\alpha}$) following Kennicutt et al. (2009):

$$SFR(M_{\odot} yr^{-1}) = 5.5 \times 10^{-42} L(H\alpha),$$

where $L(H\alpha)$ is the luminosity, calculated as

$$L(H\alpha)[erg/s] = 4\pi D^2 (3.086 \times 10^{24})^2 F_{H\alpha},$$

with $D$ the distance to the galaxy in Mpc (Table 1) and $F_{H\alpha}$, the flux corrected for Galactic absorption, as taken from NED and obtained from the Schlafly & Finkbeiner (2011)
A mass range of 0.1–100 \( \odot \) map. Equation 1 assumes a Kroupa (2001) stellar IMF with recalibration of the Schlegel, Finkbeiner & Davis (1998) dust multi-armed (M).

ones that do not have H\( ^\alpha \) emission within the bar or to galaxies that do not have an arm classification. (*) These galaxies do not have an arm classification in the CVRHS, but as their arm classification in Elmegreen & Elmegreen (1987) was 5, we have classified them as multi-armed (M).

Table 5. Non-circular motions as measured in the bar (column II), SAR (column III) and spiral arms (column IV) of the galaxies of the sample. We use the 95% value of the cumulative distribution function which we use as a representative overall measure of the residual velocities. Column V) Bar strength (\( Q_0 \)) measured from the torque maps derived from the 3.6 \( \mu \)m images (S. Díaz-García et al. in prep). Column VI) B/T from the 2D decompositions to the 3.6 \( \mu \)m images [Salo et al. 2015]. Column VII) Arm class (AC) classification from the CVRHS: F=face-on, M=multi-armed, G=grand design. The "\(^a\)" refers to non-barred galaxies, to those barred ones that do not have H\( ^\alpha \) emission within the bar or to galaxies that do not have an arm classification. (*) These galaxies do not have an arm classification in the CVRHS, but as their arm classification in Elmegreen & Elmegreen (1987) was 5, we have classified them as multi-armed (M).

recalibration of the Schlegel, Finkbeiner & Davis (1998) dust map. Equation 1 assumes a Kroupa (2001) stellar IMF with a mass range of 0.1–100 \( \odot \), an electron temperature of \( T_e = 10^4 \) K and electron density \( n_e = 100 \) cm\(^{-3}\), whereas variations in \( T_e \) from 5000 to 20000 K would result in a variation of the calibration constant (5.5 \( \times \) 10\(^{-2}\)) of \( \sim 15\% \). Variations of \( n_e = 100 – 10^3 \) cm\(^{-3}\) would result in variations in the calibration constant below 1\% (Osterbrock & Ferland 2006). This calibration also assumes that over timescales \( >6 \) Myr, star formation needs to remain constant, and no information about the previous star formation history is given (see Kennicutt & Evans 2012).

The uncertainties in the measurements of the SFR come from: mainly due from the distance, with a typical 20% uncertainty estimated for the distance value, basic reduction processes (i.e. flat-fielding correction, around 2%), the zeropoint calibration (3%, in agreement with the value of 2% typical for photometric nights), uncertainty in the flux measurement (1%) and continuum-subtraction process (around 11%). Altogether, taking into account the uncertainties related to the quality of the image (without considering the distance) we estimate an uncertainty of 17%.

To consider only star formation, we have to take into account that some of the galaxies of our sample have nuclear activity: NGC 918 (no specific classification; Palumbo, Tanzella-Nitti & Vettolani 1983); NGC 4151 (Seyfert type 1.5; Khachikian & Weedman 1974) and NGC 4639 (Seyfert 1.0; Ho, Filippenko & Sargent 1997), where all nuclear activity classifications have been collected in Véron-Cetty & Véron (2006). The Ho emission in these cases is not all coming from star formation, so the derived SFRs in these galaxies should be understood as upper limits. We have masked the nuclear emissions in these three cases and excluded them from the integration (very small in the cases of NGC 918 and the low-luminosity AGN of NGC 4639), so that the global Ho luminosities are not biased due to AGNs. NGC 3504 on the other hand is a starburst galaxy (Baldendo 1983) with a large amount of star formation in its centre.

In Fig. 3 we present the SFR as a function of the morphological T-type (from the CVRHS). Excluding the starburst galaxy (which stands out in the plot as a filled green
diamond), we find the same trend as widely found in the literature (e.g., Phillips 1993; Kennicutt 1994; Kennicutt 1998 and references therein): early-type galaxies tend to have low SFRs, intermediate-type spirals have the highest SFRs and very late-type spirals and irregulars have lower SFRs than the intermediate-type ones, although higher than those of galaxies of the earliest types. Although our sample is small, we confirm that the presence of a bar does not affect the global SFR (e.g., Phillips 1993; Kennicutt 1994; and references therein; James et al. 2004; Fisher 2006). A Kolmogorov-Smirnov (K-S) test on both the barred and the non-barred distributions with respect to the SFR results in a $P$-value of 0.094. This $P$-value indicates the relationship between both distributions, and in this case, it means that both the barred and the non-barred distributions with respect to the SFR are very similar.

From our ACAM images, we have measured the total SFRs for the galaxies of our sample, and also the SFRs for each of the defined regions. In Table 6, we present the resulting SFRs (total, bar, SAR and arms).

6 DATA RELEASE

All the data discussed here are released publicly with the publication of this paper: raw but reduced cubes (de-rotated, phase corrected and wavelength calibrated cubes), continuum-subtracted cubes, 0th, 1st and 2nd order momentum maps and continuum-subtracted Hα images. The data are available in FITS format through the NED and the Centre de Données Stellaires (CDS).

7 DISCUSSION

In this section we will discuss critically the data and data quality, and the results from our analysis in terms of kinematical parameters and non-circular motions. We will not analyse here the rotation curves as they will be studied in depth in the forthcoming Paper III (Erroz-Ferrer et al., in prep.).

7.1 Data quality

We first discuss how our observing, reduction and analysis procedures have led to caveats and constraints on the data quality.

7.1.1 Effects from the nature of the Hα data

One of the scientific goals of this kinematical survey is the study of the inner parts of the rotation curves, exploiting the high angular resolution provided by GH0Fas data. To do so, we have tried not to change the angular resolution when reducing the data, as would have been the case when using large spatial smoothing kernels or adaptive binning methods. As the data are made public, the user can always choose to adopt another smoothing kernel depending on scientific interest.

Normally, Hα data have a typical patchy appearance with many blank spaces in between the HII regions. As we have hardly smoothed the data spatially, this effect is rather obvious in most of our data. The data set contains galaxies with high signal and less patchy appearance (such as NGC 2748 or NGC 5678), and also galaxies with low signal and patchier appearance (e.g., NGC 691 or NGC 918). Consequently, the process of deriving rotation curves is difficult and leads to unsampled radial regions or bad radial sampling. For example, the central regions of the galaxies NGC 428, NGC 4151, NGC 4324, NGC 4639, NGC 5334, NGC 5740 and NGC 5921 are not sampled and can not be studied.

7.1.2 Kinematical parameters versus photometric parameters

Another caveat (though related to the first point) is the determination of the kinematical parameters $i$, $PA$ or $v_{sys}$. We explained in Sect. 5.1 how we have derived our rotation curves using rotcur in GIPSY. Due to the nature of our data, it is not easy to determine the kinematical parameters, and it is more often reliable to use other types of data, with full spatial coverage and full spatial sampling albeit at lower angular resolution. Thus, in our fits we have used Ht-derived parameters, whenever possible, as initial conditions. We also use the photometric information provided by the ellipse fitting analysis on the $S^4G$ 3.6 µm images by Muñoz-Mateos et al. (in prep), although our results do not always match the photometric results (see Table 3 for a comparison).

Regarding the PA, the PV diagrams and the position of the minor axis in our velocity maps are good tracers of the kinematical PA, so the results from rotcur describe the gas motion better than the photometric results. There is one case with a high discrepancy: NGC 4151 with $PA_{halpha}=20°\pm 3°$ (the real difference is the same as with $PA_{halpha}=180°+20°=200°$, that is 49.4°). After an inspection of the continuum-subtracted cube, and also by looking at the velocity map (panel b of Fig. A8 bottom) we have found that the PA is closer to 0°, very different from the 150° derived from the $S^4G$ image. [Ref: Bosma, Ekers & Lequeux (1977)].
discussed the first H\textsc{i} synthesis maps of this galaxy, along with a deep photograph by Arp showing the outer spiral. They found that the PA\textsubscript{kin}=19\degrees \pm 4\degrees, much closer to our PA\textsubscript{H\alpha} than to PA\textsubscript{phot}. We confirm Bosma’s conclusion: the photometric image detects only the oval distribution of the galaxy.

In the same way, there are other galaxies in the sample where the mid-IR morphology results in PA\textsubscript{phot} different from PA\textsubscript{kin}, but our PA\textsubscript{kin} agree with previous values of PA\textsubscript{kin} found in the literature. These are presented in Table 7. All the galaxies in Table 7 are barred (NGC 2805 is classified as SA in the CVRHS, but is claimed to host a bar in the 2D structural decomposition of the S\textsuperscript{4}G images, Salo et al. 2015). Therefore, the differences between the photometric and kinematic PA may well be explained with the presence of the bar which, depending on its orientation, influences the kinematics in the bar region and causes deviations from pure circular motions (see Sect. 7.2). Also, irregular outer spiral arms (such in NGC 6412) can influence on the measurements of PA\textsubscript{phot}, and we conclude that PA\textsubscript{kin} trace the real PA better than PA\textsubscript{phot}.

As for the inclination, the largest discrepancies occur in NGC 4151 (already discussed), and in NGC 2748 and NGC 3504, where the inclinations as derived from the kinematic data are substantially higher than those derived from the surface photometry. This can be due to the non-uniform distribution of the H\textsc{i} regions as compared to the distribution of the stars and dust as seen in the S\textsuperscript{4}G 3.6 \textmu m images. NGC 2748 shows a bulge at faint light levels, hence the discrepancy in inclination. NGC 3504 has a low inclination, seen in the S\textsuperscript{4}G image. Also, NGC 2748 and NGC 3504 host an outer ring (R’ and R’\textsuperscript{1}, respectively), not seen in H\textalpha.

### Table 6. SFRs measured from the ACAM H\alpha images, corrected for Galactic absorption (see text). Notes: The “-” refers to non-barred galaxies or to those barred ones that do not have H\alpha emission within the bar. (*) The AGN contribution has been excluded from the measurements.

7.1.3 Comparison with literature data

In the Introduction, we mentioned the H\alpha FP kinematic surveys of Garrido et al. 2002 (GHASP), Daigle et al. 2006a (SINGS sample) and Chemin et al. 2006 (VIRGO sample). These surveys have used instrument similar to GHoFaS: Cigale and FaNTOmM (FabryPerot de Nouvelle Technologie de l’Observatoire du Mont Mélangiac\textsuperscript{3}). These were mounted at different telescopes: the 3.6 m Canada-France-Hawaii Telescope (VIRGO and SINGS), the 3.6 m European Southern Observatory telescope (VIRGO), the 1.93 m Observatoire de Haute-Provence telescope (VIRGO, SINGS and GHASP), and the 1.60 m Observatoire du Mont Mélangiac telescope (VIRGO and SINGS). All these data are seeing-limited, but taken under observing conditions worse.

\textsuperscript{3} http://www.astro.umontreal.ca/fantomm
than ours (less than 2″ seeing in the very best cases, but with seeing values of 8″-12″ in the worst cases). In Table 8 we show the different quality characteristics of these surveys as compared to our GHzaS data.

The reduction techniques used in these surveys are based on the University of Montréal Improved 3D Fabry-Perot Data Reduction Technique[^1] and are summarised in Daigle et al. (2006b). The most important reduction steps that differ from ours are spectral and spatial smoothing. The three surveys smooth the data spectrally (that is, in the wavelength direction), with three-channel or Hanni-filtering smoothing. Also, they use the Voronoi adaptive binning method [^2] (Cappellari & Copin 2003), which consists of gathering as many pixels as necessary in order to achieve a threshold value of the signal-to-noise ratio for the considered bin. Hence, the Voronoi method allows maximum spatial resolution for regions with strong emission and good signal-to-noise values for regions with low emission.

On the contrary and with the goal of keeping the highest spectral and angular resolution possible throughout, we have not smoothed the data spectrally and applied a median spatial smoothing of 3×3 pixels. These reduction procedures have been chosen following our scientific goals of studying the inner parts of the rotation curves and studying streaming motions within the different galaxy substructures.

In Fig. 7 we compare the velocity fields of three galaxies in the overlap of our sample with that of GHASP (NGC 864, NGC 2500 and NGC 2543) and two galaxies in the overlap with the VIRGO sample (NGC 4498 and NGC 4639). We compare the velocity fields as obtained from the GHzaS, GHASP and VIRGO data by different reduction methods: ours, as explained in Sect. 4 and following the reduction techniques used for the GHASP and VIRGO surveys (three-channel spectral smoothing and Voronoi adaptive binning, see Chenin et al. 2006 and Epinat, Amram & Marcelin 2008). In these figures, it is possible to compare directly the advantages and disadvantages of each reduction procedure. On the one hand, we see that one drawback of following the reduction steps of Sect. 4 is that the spatial coverage is limited to the location of the Hii regions, resulting in patchy maps. But on the other hand, Voronoi smoothing reduces the angular resolution often to that typical of Hii data (6″-10″). With the results from the adaptive binning, it is very difficult to perform studies inside the structures of the galaxies (such as bars or spiral arms), as they cannot be resolved any more. This includes the study of the streaming motions (this paper), and of the inner parts of the rotation curves (Paper III). As explained in Sect. 6, we publish our raw and basic reduced data, and any worker interested in smoothed versions of our data sets, either spectrally or Voronoi, can simply download the data and perform their own favourite recipes.

In Fig. 8 we present the velocity field of the central part of NGC 2543 to show the differences between the GHzaS and GHASP data, both reduced following the techniques explained in the current paper. The differences arising from the different pixel scale (0′′.2 of GHzaS against 0′′.68 of GHASP) and different seeing conditions (1′′.3 for our observations against 3′′.7 for GHASP) can clearly be seen.

To see the possible impact of the different reduction processes, we also compare the rotation curves of the overlapping galaxies. In Fig. 9 we superimpose the rotation curves from GHASP and VIRGO papers onto our rotation curves for the galaxies in Fig. 7. Erroz-Ferrer et al. (2012) give a direct comparison between the rotation curve of NGC 864 from our data and that of GHASP, so this galaxy has not been included in Fig. 9. For completeness, we compare the rotation curves of the remaining overlapping galaxies in Figs. B1-B4. There are many similarities and the rotation curves agree reasonably. The possible discrepancies mainly come from the different parameters (v, i and PA) used for the fits to the velocity fields. Also, the spatial coverage resulting from the different reduction techniques is reflected in the rotation curves: smoothing kernels such as Voronoi help to highlight the emission in the low-signal regions, but compromise the spatial resolution.

### 7.2 Non-circular motions

One of the aims of this kinematical study is to analyse the influence of the galaxies’ main structural features on their kinematics. In other words, we want to study the kinematical footprints of the components of the galaxies, traced for instance by the non-circular motions. Deviations from pure circular motion have been widely studied previously in the literature. The first studies of streaming motions induced by the spiral density waves were presented by Bosma (1978), Visser (1980) and Rots et al. (1990) using Hα data; by Ichikawa et al. (1985), Clemens (1985) and Cepa et al. (1992) using CO data, and by van der Kruit (1976) and Marcelin, Boulesteix & Georgelin (1985) using Hα data. They confirm what Roberts (1969) had predicted theoretically: variations of 10 – 30 km s^{-1} in the velocity are found when the gas crosses the density wave. Bar-induced non-circular motions have also been analysed in the literature, and the first

7.2.1 Bar-induced non-circular motions

We are interested in analysing kinematically the effects of secular evolution by investigating the effects of the presence of a bar on the rotation of the galaxies. Our kinematic data allow us to study the kinematics and the star formation at the same time, with the caveat that we are only observing the star-forming regions. Our first goal is to understand the connection between the presence of a bar and the kinematics within the bar region. Our second goal is to study the link to star formation within the bar.

In Sect. 5.2 we explained how we computed a non-circular motions map, the residual velocity field. These residual velocity fields depend significantly on the derived rotation, that is, on the rotation curve derived from the observed velocity field. Consequently, a rigorous analysis of the output of the ROTCUR task in GIPSY has been carried out. We want to study both non-circular motions caused by the spiral density waves (hereafter spiral-induced non-circular motions) and those caused by the gravitational potential of the bar (bar-induced non-circular motions). The galaxies in our sample span a wide variety of morphological types and features, so a statistical approach to the non-circular motions is possible, though not straightforward.

### Table 8. Characteristics of the Hα FP kinematical surveys of Garried et al. (2002) (GHASP), Daigle et al. (2006) (SINGS sample) and Chemin et al. (2006) (VIRGO sample), shown along with the characteristics of the data used in this paper. Note) The '-' denotes that there are no galaxies with that criteria (VIRGO, GHASP and this paper), or that no information about the seeing was presented (SINGS). (*+ Information before the reduction processes (i.e., before smoothing).

| Parent survey | VIRGO | SINGS | GHASP | S^G (this paper) |
|---------------|-------|-------|-------|------------------|

| Spectral sampling(*) | 7 - 14 km s^{-1} | 7 - 14 km s^{-1} | ~10 km s^{-1} | ~8 km s^{-1} |

Studies were performed by Peterson et al. (1978), Duval & Athanassoula (1983) and Pence et al. (1988) using optical data, and by Sancisi, Allen & Sullivan (1979) and Gottesman et al. (1984) using HI data. They found that the isovelocity contours tend to go parallel to the bar rather than parallel to the minor axis. Also, they found some cases where these deviations from the circular motion are more prominent when the PA_{BAR} is at ∼ 45° from the kinematic major axis (in agreement with the models by, e.g., van Albada & Roberts 1981). The nature and characterisation of these non-circular motions is a topic still under debate, and many studies of the streaming motions have been performed (e.g., Knapen et al. 2000, Fresneau, Vaughan & Argyle 2005, Spekkens & Sellwood 2007, Castillo-Moraes et al. 2007, Shetty et al. 2007, Tamburri et al. 2008, Garcia-Burillo et al. 2009, Sellwood & Sánchez 2010, Meidt et al. 2013, Font et al. 2014b).

In the other galaxies (NGC 2543, NGC 2712, NGC 5740 and NGC 5921) the bar itself does not appear in Hα, but the surrounding regions (mostly the SAR) show large non-circular motions. We have also measured the non-circular motions in the SAR in all other barred galaxies, and along the spiral arms of all galaxies. NGC 4324 is a lenticular galaxy, so there we have measured the residual velocities along the ring instead of the arms, finding values of 16.2 ± 3.2 km s\(^{-1}\).

The PV diagrams along the minor axis presented in Appendix C are the first clue to see that there are deviations from circular motion. As illustrated for NGC 864 in Paper I, in the absence of non-circular motions, the velocity profile along the minor axis should be completely flat. For most of the barred galaxies in our sample, there are deviations from the systemic velocity, presented as peaks or troughs in the velocity profile along the minor axis. These indicate that some gas along the minor axis is not following the rotational pattern of the galaxy. As we see in NGC 864 (Fig. C5), NGC 3504 (Fig. C6) or NGC 5678 (Fig. C7), the deviations from the systemic velocity are found beyond the extent of the bar. This implies that the non-circular motions outside the bar region (i.e., in the SAR) can be a result of the influence of both potentials (bar and spiral arms).

In Fig. 11 (left) we represent the residual velocities in the bar region (and normalised) as a function of the difference between the major axis of the bar and that of the kinematic major axis, ΔPA. We see that the amplitude of the non-circular motions here does not increase as ΔPA approaches 45°, contrary to the expectation.
Figure 7. Comparison between the data obtained with the GHαFaS instrument and data from GHASP (NGC 864, NGC 2500 and NGC 2543) and VIRGO (NGC 4498 and NGC 4639).

Column I) DSS image. Column II) ACAM Hα image. Column III) Velocity field from GHαFaS observations, obtained following the reduction procedures described in Sect. 4. Column IV) Velocity field from GHASP/VIRGO observations, obtained following the reduction procedures described in Sect. 4. Column V) Velocity field from GHαFaS observations following the reduction processes of GHASP/VIRGO data (three-channel spectral smoothing and Voronoi adaptive binning). Column VI) Data from GHASP (Epinat, Amram & Marcelin 2008) and VIRGO (Chemin et al. 2006) surveys. Note) For NGC 2543, the central region has been marked with a black square and explicitly shown in Fig 8.

regions -bar (Fig. 11a), SAR (Fig. 11d) and spiral arms (Fig. 11g)- as a function of the bar strength, quantified by the torque parameter \( Q_b \). \( Q_b \) is strongly reacting to the bulge: a stronger bulge dilutes the tangential force from the bar and lowers \( Q_b \). It is not necessarily true that the bar is weaker, just that motions are more controlled by the spherical potential of the bulge. Therefore, to distinguish the influence of the bulge in the bar strength, we have also studied the non-circular motions as a function of the bulge-to-total ratio \( B/T \) in the middle plots of Fig. 11: bar (Fig. 11b), SAR (Fig. 11e) and spiral arms (Fig. 11h). Also, in all the plots, we have presented the galaxies with \( B/T < 0.1 \) with blue asterisks, galaxies with \( 0.1 < B/T < 0.2 \) with red triangles, and galaxies with \( B/T > 0.2 \) (bulge dominated) with squares. We list the \( Q_b \) and \( B/T \) values for the galaxies of our sample in Table 5. In plots Fig. 11(a,b,c,d,e,f,g) we only represent those cases where a galaxy has a bar (i.e., \( Q_b \neq 0 \)). The same plots as in Fig. 11 have been created for the normalised residual velocities, and are presented in Fig. 12.

Analysing the left hand plots of Figs. 11 and 12(a,d,g), we conclude that \( Q_b \) does not correlate with the amplitude of the non-circular motions. Also, the middle plots of Figs. 11(b,e,f) show no correlation between the amplitude of the non-circular motions and the presence of a bulge. Although the few cases with a significant bulge \( (B/T > 0.1) \), show that the residual velocities in the bar decrease as \( B/T \) increases, more data would be needed to prove whether the bulge is constraining the velocities to remain circular.
Figure 9. Hα rotation curves for NGC 2500, NGC 2543, NGC 4498 and NGC 4639. Black diamonds correspond to the high-resolution rotation curves derived from GHαFaS data (this paper). Red asterisks and blue triangles correspond to approaching and receding rotation curves from GHASP data. Pink squares correspond to VIRGO data.

We have measured the luminosities from the three regions identified previously in the galaxies of the sample (bar, SAR and spiral arms), and derived the SFRs in those regions using the equations presented in Sect. 5.3. In panels Fig. 11c and Fig. 12c, we see a slight tendency that the higher non-circular motions correspond to star forming bars, or to bars that show more Hα emission (note that the scale in SFR is logarithmic). This is surprising as in the literature, the high shear and shocks in the bar region prevent star formation (e.g., Athanassoula 1992; Reynolds & Downes 1992; Zurita et al. 2004; Martinet & Friedli 1997). Martinet & Friedli (1997) found that the highest SFRs along the bar correspond to the stronger and longer bars in their sample of isolated late-type barred galaxies.

In Fig. 13, we present the resulting SFR values within the bar and SAR of our sample galaxies as a function of \(Q_b\), a parameter which quantifies the strength of the bar and consequently that of shocks/shear. From Fig. 13 we conclude that the bar strength does not determine the presence or quantity of Hα emission along the bar. In our sample, we see that the strongest bars (\(Q_b, NGC1073=0.63\) and \(Q_b, NGC5112=0.62\)) show Hα emission, but further study is needed to see if this emission is located in the regions of high shocks/shear. (i) García-Barreto et al. (1996) found that the barred galaxies with Hubble types SBa or earlier in their sample did not show Hα emission, probably due to the low gas content available for inflow (which is not the case, for example, for NGC 4151) so the morphological type is not in principle the only reason. (iii) Martin & Friedli (1997) also found that the two highest SFRs correspond to the galaxies which present the strongest signs of recent interaction or merging (NGC 4731 and NGC 7479). (iv) Sheth et al. (2000) came to the conclusion that the stars in NGC 5383...
Figure 11. Measurements of the non-circular motions. The top plots represent the non-circular motions (residual velocities from the 95% of the CDF) in the bar region, whereas the middle and bottom plots represent the residual velocities in the SAR and arms respectively. Left) Residual velocities as a function of the bar strength (represented by the parameter $Q_b$ from Díaz-García et al. in prep). The galaxies without a bar (i.e., $Q_b=0$) have not been represented. Middle) The same residual velocities as a function of $B/T$. Right) The same residual velocities as a function of the SFR in each of the three regions. Note: In all the plots, we have represented galaxies with $B/T<0.1$ with blue asterisks, galaxies with $0.1<B/T<0.2$ with red triangles, and galaxies with $B/T>0.2$ (bulge dominated) with squares. In the top right plot, we have highlighted with a filled green square the starburst nucleus (NGC 3504).

may have been formed in the spurs before the gas encounters the dust lane, and travel ballistically through the shock at the dust lane, ionizing the regions located at the leading side of the dust lane. V. Verley et al. (2007) suggested that the presence of star formation in the central region and along bars is a consequence of an evolutive sequence, that goes from galaxies with H$\alpha$ in the bar to galaxies with H$\alpha$ emission in the circumnuclear region but not within the bar, ending in galaxies without any emission either along the bar or in a central knot.

We conclude that there is no simple answer to the question why some bars have current star formation and others don’t. The answer is probably a combination of the previous features. With our sample of galaxies, we find that neither the Hubble type nor the bar strength determine the presence of H$\alpha$ emission within the bar region, but larger samples are needed to establish well-based statistical results on the SF within bars. Furthermore, deeper and higher-resolution kinematic data (e.g., from the Atacama Large Millimeter/submillimeter Array, ALMA) would enable the study of the physical conditions in the bar related to the formation of stars at the scales of the molecular clouds. Then, it may be possible to understand if a recent interaction or merger is causing the star formation of the bar, if the galaxy has already used up the available gas to be transformed into stars, or if the location of the shocks and shear correspond to regions of diminished star formation.

7.2.2 Spiral-induced non-circular motions

In the bar region, the mechanisms triggering star formation may be different from those in spiral arms, due to the different dynamics and shock conditions. In Fig. 14 we show star formation within the spiral arms and the amplitude of the non-circular motions there as a function of the arm class, a parameter which might plausibly be related to the “strength” of the spiral arms. We do not find any trend or correlation. Elmegreen & Elmegreen (1986) found that the SFR per unit area does not depend on the arm class, and we confirm this. Therefore, we agree with other studies which
confirm that the SFR does not depend on the strength of the arms (Dobbs & Pringle 2009; Foyle et al. 2010), and disagree with those that confirm the opposite (e.g., Seigar & James 2002; Clarke & Gittins 2006). The presence and magnitude of streaming motions in the arms seem to be a local phenomenon, unrelated to the SFR or arm class.

The high amplitude of the non-circular motions found in NGC 5678 (with a representative value of \(\sim 70\) km s\(^{-1}\) above the average 20-30 km s\(^{-1}\) for spiral-induced non-circular motions) leads us to consider that a spiral cannot be the single cause, and that this galaxy could be barred. This galaxy was classified as SAB in de Vaucouleurs et al. (1991) and argued to be barred by Ganda et al. (2007), but the CVRHS reclassified it as SA from an S\(^4\)G mid-IR image and therefore does not have a value for \(Q_b\). The PV diagram along the minor axis (Fig. C7) shows the deviations from the circular motions, very similar to those created by the potential of the bar in NGC 864 (Paper 1). We conclude that the non-circular motions in NGC 5678 are an evidence supporting the claim that NGC 5678 is a barred galaxy, and the high amplitude of those non-circular motions could be bar-induced rather than only spiral-induced. Another interpretation could be that there was a recent minor merger. The galaxy is asymmetric in the integrated H\(^\alpha\) map, contrary to the expectations of a symmetric bar.

8 CONCLUSIONS

In this paper we present the data from the kinematical study of S\(^4\)G galaxies which started in Paper I, and reach the following conclusions:

(i) We have completed the observations of our kinematical study of 29 S\(^4\)G spiral galaxies of all morphological types using the GHoFaS FP instrument (FOV of 3.4 \(\times\) 3.4 arcmin). The data have seeing limited angular resolution (typical values between 0.6 and 1.4 arcsec) sampled with 0\('\)2 per pixel and a spectral sampling \(\sim 8\) km s\(^{-1}\). These FP data have been observed together with H\(^\alpha\) flux-calibrated images.

(ii) To reach our scientific objectives, we have followed specific data reduction and analysis procedures that guarantee high angular resolution (\(\sim 1''\)) kinematic cubes and data products.

(iii) The images, data described and rotation curves in
Figure 6. Comparison between the parameters inclination and position angle derived from the S4G 3.6 µm images (i.e. photometric) and derived with the tilted-ring method to our Hα FP data (i.e. kinematical). Left) Comparison of the inclinations derived photometrically and kinematically. Right) Comparison between the position angles derived photometrically and kinematically. Note: Due to our definition of the position angles (0° ⩽ PA < 180°), the difference between PA=0° and PA=179° is not 1°, but 1°.

Figure 8. Velocity fields of the central region of NGC 2543 reduced following the procedures of this paper from GHαFaS (left) and GHASP (right) observations. Note the differences due to the pixel scale (0′′.2 of GHαFaS against 0′′.68 of GHASP) and seeing conditions (1′′.3 for our observations against 3′′.7 for GHASP).

Figure 8. Velocity fields of the central region of NGC 2543 reduced following the procedures of this paper from GHαFaS (left) and GHASP (right) observations. Note the differences due to the pixel scale (0′′.2 of GHαFaS against 0′′.68 of GHASP) and seeing conditions (1′′.3 for our observations against 3′′.7 for GHASP).

this paper are publicly released through the NED and the Centre de Données Stellaires (CDS).

(iv) We flux-calibrate the GHαFaS data cubes following the procedures presented in Paper I. We conclude that the flux calibration can not be automated, and no standard calibration factors can be extracted for any particular GHαFaS filter. Instead, flux calibration is specific to each galaxy and needs to be performed by comparison with calibrated Hα images, such as our ACAM images.

(v) We have applied the tilted-ring method to our velocity maps to extract the rotation curves. Some caveats arising in the nature of these FP data need to be taken into account (e.g., intrinsic patchiness of the line emission).

(vi) We have created non-circular motion maps for all the galaxies of the sample. We confirm the presence of these non-circular motions created by the non-axisymmetric potential of the bar along the bar region and at the start of the spiral arms, with a tendency that the more star-forming bars induce higher non-circular motions. We find that Q_b does not correlate with the amplitude of the non-circular motions. However, our data is biased towards bars with recent star formation, where strong shocks and shear may take place and star formation may be inhibited.

(vii) Also, we confirm the presence of non-circular motions created along the spiral arms, but there is no correlation of the amplitude of these non-circular motions with the arm class, a parameter that is related to the arm strength.

ACKNOWLEDGMENTS

We acknowledge financial support to the DAGAL network from the People Programme (Marie Curie Actions) of the European Union’s Seventh Framework Programme FP7/2007-2013/ under REA grant agreement number PITN-GA-2011-289313, and from the Spanish MINECO under grant number AYA2013-41243-P. This work was co-funded under the Marie Curie Actions of the European Commission (FP7-COFUND). We also gratefully acknowledge support from NASA JPL/Spitzer grant RSA 1374189 provided for the S4G project. E.A. and A.B. thank the CNES for support. KS, JCMM, and TK acknowledge support from The National Radio Astronomy Observatory, which is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc. This research has been supported by the MINECO under the grant AYA2007-67625-CO2-O2, and is based on observations made with the WHT operated on the island of La Palma by the Isaac Newton Group of Telescopes, in the Spanish Observatorio del Roque de Los Muchachos of the Instituto de Astrofísica de Canarias. The authors thank the entire S4G team for their efforts in this project. We acknowledge the usage of the HyperLeda database (http://leda.univ-lyon1.fr). This research has made use of the NASA/IPAC Extragalactic Database (NED) which is operated by JPL, Caltech, under contract with NASA.
Figure 10. Top) Amplitude of the non-circular motions (residual velocities from the 95% of the CDF) in the bar region as a function of the difference between the major axis of the bar and that of the kinematic major axis, ∆PA. Contrary to what has been reported in the literature, the highest streaming motions are not found in galaxies with ∆PA ∼ 45°. Bottom) As the top panel but for the normalised residual velocities.

Figure 13. SFRs measured in the bar region (top) and in the SAR as a function of the bar strength, represented by the parameter $Q_b$. We see that in this case, the strength of the bar does not regulate the Hα luminosity. Note: Again, we have represented galaxies with $B/T < 0.1$ with blue asterisks, galaxies with $0.1 < B/T < 0.2$ with red triangles, and galaxies with $B/T > 0.2$ with squares. In the top plot, we have highlighted with a filled green square the starburst nucleus (NGC 3504) which affects only the bar region plot.
Figure 14. 

**Top)** SFR in the arms per unit area as a function of the arm class classification from the CVRHS. 

**Bottom)** Amplitude of the non-circular motions within the spiral arms as a function of the arm class. We see that neither the SFR nor the amplitude of the non-circular motions correlate with the arm class.

*Note)* NGC 4324 has not been represented in the figure as it does not have an arm class classification. NGC 5678 has not been represented either because the amplitude of the non-circular motion within its spiral arms presented in Table 5 is understood as being caused by the bar (see Sect. 7.2.2).
