ABSTRACT: We explore the discovery potential for long-lived particles at the 250-GeV ILC. The goal is to investigate possible gains of a dedicated far detector over the main detector ILD. For concreteness, we perform our study for sub-GeV axion-like particles $a$ produced via $e^+e^- \rightarrow a\gamma$ or $e^+e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$ and decaying into pairs of charged leptons. In the ideal case of zero background and perfect detection efficiency, we find that far detectors placed in the planned underground cavities or a large cuboid on the ground can enhance the sensitivity to long-lived pseudo-scalars at best moderately. On the other hand, the ILD itself is a perfect environment to search for long-lived particles, due to its excellent angular coverage and radial thickness. For long-lived particles produced with cross sections of a few picobarns, the ILD could probe lifetimes up to 300 ns, or proper decay lengths up to 100 m, in 250 fb$^{-1}$ of data. For axion-like particles produced through weak interactions, the ILC can reach an even higher sensitivity than searches for displaced vertices in meson decays at Belle II. Our findings apply similarly to other proposed electron-positron experiments with a high angular coverage, such as the FCC-ee and CEPC.
1 Introduction

Current searches for long-lived particles (LLP) are often driven by opportunism. Existing particle colliders are found to be sensitive to LLPs with a certain range of masses and couplings, which is determined by the particle source and the detector geometry [1]. For the LHC, new search strategies [2, 3], as well as several annex experiments like FASER [4, 5], MATHUSLA [6], and CODEX-b [7] have been proposed to optimize and extend the reach for LLPs.\(^1\)

For the next high-energy particle collider, it is advisable to explore the discovery potential for LLPs and optimize the detector setup before construction. The key question to answer is: Where should an LLP detector ideally be placed and with what geometry?

In this work we answer this question for future high-energy electron-positron experiments. While we focus on the International Linear Collider (ILC) [9], most of our results can be transferred to the FCC-ee [10] and CEPC [11]. Previous analyses for future \(e^+e^-\) colliders have focused on LLPs produced via Higgs or \(Z\) boson decays [12–14] or sterile neutrinos [15] and decaying in the main detector. The physics potential of far detectors has been explored at the FCC-ee or CEPC [16, 17] and at future lepton colliders running at the \(Z\) pole [18]. Alternatively, light LLPs produced from the electron or positron beams could be observed in beam dump experiments, as proposed for the ILC [19].

We conduct the first study of realistic far detector options for the ILC with a center-of-mass energy of \(\sqrt{s} = 250\) GeV. A central aspect of our work is to compare the reach for LLPs at far detectors with the main detector ILD. We perform this comparison systematically for LLPs produced with different kinematic distributions. This allows us to determine

\(^1\)FASER is currently constructed and has demonstrated its capability to detect neutrinos with a test run [8].
the key features required for a detector to be sensitive to LLPs with specific production kinematics and decay lengths. For concreteness, we focus on axion-like particles (ALPs) $a$ with masses well below the weak scale, produced via $e^+e^- \rightarrow a\gamma$ and $e^+e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$ and decaying into pairs of displaced charged leptons. These two scenarios can be considered as benchmarks for a larger class of light new particles with similar production kinematics and decay lengths, which should lead to very similar results.

The second main aspect of our work is to compare our results for the ILC with low-energy electron-positron colliders, in particular with the Belle II experiment [20]. While both experiments benefit from a clean environment and an excellent angular coverage of the main detector, the dominant production channels and decay kinematics of an LLP are very different due to the different collision energies. If and how a high-energy electron-positron collider can extend the reach for LLPs beyond Belle II is therefore a tricky question with a high impact on the discovery potential of future experiments.

This paper is structured as follows: In Sec. 2, we introduce the model used for our analysis and discuss the main production channels and kinematic distributions of axion-like particles at the ILC. In Sec. 3, we design three far detectors at the ILC and analyze how their position and geometry affects the expected event rates of decaying LLPs. In Sec. 4, we discuss the discovery potential for ALPs at the ILC far detectors in detail and compare it with the ILD. In Sec. 5, we compare the sensitivity at the ILC with ALPs from meson decays at Belle II, before concluding in Sec. 6.

2 Axion-like particles at the ILC

Axion-like particles (ALPs) are pseudo-scalars that could originate as pseudo Nambu-Goldstone bosons from a chiral symmetry broken at a scale $\Lambda$ and whose couplings respect a shift symmetry $a \rightarrow a + c$. We focus on a benchmark model with ALPs coupling only to light leptons $\ell = \{e, \mu\}$ and weak gauge fields. At energies above the weak scale, $\mu_w$, the ALP couplings are described by an effective Lagrangian [21]

$$L_{\text{eff}}(\mu > \mu_w) = \frac{c_\ell}{2} \frac{\alpha^2}{f_a} (\tilde{\ell} \gamma_\mu \gamma_5 \ell) + c_{WW} \frac{\alpha^2}{4\pi f_a} W_{\mu\nu}^* W_{\tau\mu\nu},$$

where $c_\ell$ denotes the ALP coupling to leptons, and $c_{WW}$ is the coupling to weak gauge bosons with field strength tensor $W_{\mu\nu}^\tau$. The latter is normalized to the weak gauge coupling $\alpha_2 = \alpha/s_w^2$, with the fine structure constant $\alpha$ and the sine of the weak mixing angle, $s_w = \sin \theta_w$. The effective theory is valid at energies up to a cutoff scale $\Lambda = 4\pi f_a$, where it is to be completed by a full model. For the QCD axion, the scale $f_a$ is related to the axion decay constant.

Below the scale of electroweak symmetry breaking, the ALP interactions with photons and $Z$ bosons read

$$L_{\text{eff}}(\mu < \mu_w) \supset \frac{\alpha}{4\pi f_a} \left( c_{\gamma\gamma} F_{\mu\nu} \tilde{F}^{\mu\nu} + 2 \frac{c_{\gamma Z}}{s_w^2 c_w} F_{\mu\nu} \tilde{Z}^{\mu\nu} + \frac{c_{ZZ}}{s_w^4 c_w^2} Z_{\mu\nu} \tilde{Z}^{\mu\nu} \right),$$

This paper is structured as follows: In Sec. 2, we introduce the model used for our analysis and discuss the main production channels and kinematic distributions of axion-like particles at the ILC. In Sec. 3, we design three far detectors at the ILC and analyze how their position and geometry affects the expected event rates of decaying LLPs. In Sec. 4, we discuss the discovery potential for ALPs at the ILC far detectors in detail and compare it with the ILD. In Sec. 5, we compare the sensitivity at the ILC with ALPs from meson decays at Belle II, before concluding in Sec. 6.

2 Axion-like particles at the ILC

Axion-like particles (ALPs) are pseudo-scalars that could originate as pseudo Nambu-Goldstone bosons from a chiral symmetry broken at a scale $\Lambda$ and whose couplings respect a shift symmetry $a \rightarrow a + c$. We focus on a benchmark model with ALPs coupling only to light leptons $\ell = \{e, \mu\}$ and weak gauge fields. At energies above the weak scale, $\mu_w$, the ALP couplings are described by an effective Lagrangian [21]

$$L_{\text{eff}}(\mu > \mu_w) = \frac{c_\ell}{2} \frac{\alpha^2}{f_a} (\tilde{\ell} \gamma_\mu \gamma_5 \ell) + c_{WW} \frac{\alpha^2}{4\pi f_a} W_{\mu\nu}^* W_{\tau\mu\nu},$$

where $c_\ell$ denotes the ALP coupling to leptons, and $c_{WW}$ is the coupling to weak gauge bosons with field strength tensor $W_{\mu\nu}^\tau$. The latter is normalized to the weak gauge coupling $\alpha_2 = \alpha/s_w^2$, with the fine structure constant $\alpha$ and the sine of the weak mixing angle, $s_w = \sin \theta_w$. The effective theory is valid at energies up to a cutoff scale $\Lambda = 4\pi f_a$, where it is to be completed by a full model. For the QCD axion, the scale $f_a$ is related to the axion decay constant.

Below the scale of electroweak symmetry breaking, the ALP interactions with photons and $Z$ bosons read

$$L_{\text{eff}}(\mu < \mu_w) \supset \frac{\alpha}{4\pi f_a} \left( c_{\gamma\gamma} F_{\mu\nu} \tilde{F}^{\mu\nu} + 2 \frac{c_{\gamma Z}}{s_w^2 c_w} F_{\mu\nu} \tilde{Z}^{\mu\nu} + \frac{c_{ZZ}}{s_w^4 c_w^2} Z_{\mu\nu} \tilde{Z}^{\mu\nu} \right),$$
with the field strength tensors of the photon, $F_{\mu\nu}$, and the $Z$ boson, $Z_{\mu\nu}$, and the couplings
\[ c_{\gamma\gamma} = c_{WW}, \quad c_{\gamma Z} = c_{WW}^2, \quad c_{ZZ} = c_{WW}^4. \tag{2.3} \]

At the ILC running with a center-of-mass energy of $\sqrt{s} = 250$ GeV, ALPs can be efficiently produced through the coupling $c_{WW}^2$ via two main production channels
\[ e^+e^- \rightarrow a\gamma \quad \text{and} \quad e^+e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma. \tag{2.4} \]

Illustrative Feynman diagrams are shown in Fig. 1. In $e^+e^- \rightarrow a\gamma$, the ALP is directly produced in association with a photon; the cross section scales as $\sigma(e^+e^- \rightarrow a\gamma) \sim c_{\gamma\gamma}^2$. In $e^+e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$, the production proceeds through an on-shell $Z$ boson, which decays with a branching ratio $B(Z \rightarrow a\gamma) \sim c_{\gamma Z}^2$, so that
\[ \sigma(e^+e^- \rightarrow (a\gamma)\gamma) \equiv \sigma(e^+e^- \rightarrow Z\gamma) B(Z \rightarrow a\gamma). \tag{2.5} \]

At $\sqrt{s} = 250$ GeV and with unpolarized beams, the ALP production rates are given by
\[ \sigma(e^+e^- \rightarrow a\gamma) = 298 \left( \frac{c_{WW}}{f_a [\text{TeV}]} \right)^2 \text{fb}, \quad \sigma(e^+e^- \rightarrow (a\gamma)\gamma) = 144 \left( \frac{c_{WW}}{f_a [\text{TeV}]} \right)^2 \text{fb}. \tag{2.6} \]

The production rates depend little on the ALP mass, as long as it is well below the $Z$ boson mass. In our numerical analysis we set
\[ \frac{c_{WW}}{f_a} = \frac{1}{\text{TeV}} \quad \text{and} \quad m_a = 300 \text{ MeV}, \tag{2.7} \]

unless specified otherwise.

The lifetime and decay channels of the ALP, however, depend strongly on its mass and couplings. In our analysis, we assume that the ALP decays to 100% into muons.\(^4\) The

\(^2\)The ALP production from electrons is strongly suppressed by the small electron mass.
\(^3\)Compared to $e^+e^- \rightarrow a\gamma$, ALP production through weak boson fusion, $e^+e^- \rightarrow \ell e^+e^-$ or $e^+e^- \rightarrow \ell\ell\bar{\nu}$, is smaller by about an order of magnitude.
\(^4\)Strictly speaking, for the benchmark scenario built on (2.1) the decay $a \rightarrow \mu^+\mu^-$ dominates over $a \rightarrow \gamma\gamma$ for $c_{\ell\ell}/c_{WW} \gtrsim 0.002$ at $m_a = 300$ MeV. We also allow for decays to electrons, which however are strongly suppressed and negligible for ALPs with masses above the di-muon threshold.
ALP decay width is
\[
\Gamma(a \rightarrow \mu^+\mu^-) = \frac{m_a m_\mu^2}{8\pi} \left( \frac{c_\ell}{f_a} \right)^2 \sqrt{1 - \frac{4m_\mu^2}{m_a^2}},
\]  
(2.8)
where \(m_\mu\) is the muon mass. For \(m_a = 300\) MeV, the proper decay length of the ALP is given by
\[
c_\tau_a = \frac{c}{\Gamma(a \rightarrow \mu^+\mu^-)} \approx 50 \left( \frac{f_a [\text{TeV}]}{c_\ell} \right)^2 \mu\text{m}.
\]  
(2.9)

The decay length observed in the laboratory frame, \(d = (\beta\gamma)_a c_\tau_a\), is related to the proper decay length \(c_\tau_a\) by the boost \((\beta\gamma)_a\). Most of our analysis relies on the production kinematics and decay length of the ALP. Using (2.6) and (2.9), the results can be translated to other light (pseudo-)scalars with different decay modes, as long as the production kinematics are similar.

The rate of ALP decays inside a detector depends not only on the ALP decay length, but also on its kinematic distributions. In Fig. 2, we show the differential distributions of the ALP in energy \(E_a\), transverse momentum \(p_a^T\), and scattering angle \(\theta_a\) off the electron beam for the two production processes \(e^+e^- \rightarrow a\gamma\) and \(e^+e^- \rightarrow (a\gamma)\gamma\). All kinematic variables are defined in the laboratory frame, which corresponds with the \(e^+e^-\) center-of-mass frame.

For \(e^+e^- \rightarrow a\gamma\), the energy of the two final-state particles is peaked at \(E_a = \sqrt{s}/2 = 125\) GeV. This is also reflected in the transverse momentum spectrum of the ALP, which peaks near \(p_a^T \approx 125\) GeV. The angular distribution favors ALP emission perpendicular to the beam axis, near \(\theta_a \approx \pi/2\).

For \(e^+e^- \rightarrow (a\gamma)\gamma\), the kinematic distributions look very different, due to the intermediate on-shell \(Z\) boson. The cross section for \(e^+e^- \rightarrow Z\gamma\) features a collinear enhancement in the forward region, see e.g., (7) in [22], so that the \(Z\) boson is emitted along the beam line. Due to momentum conservation, the ALP in \(Z \rightarrow a\gamma\) is produced either in or against the direction of the \(Z\). In the former case the ALP carries the energy of the \(Z\) boson, \(E_a \approx 125\) GeV, while in the latter case the ALP carries just enough momentum to balance the recoil of the two photons. This explains the enhancement in the energy spectrum near the kinematic endpoints, as well as the enhancement in the forward and backward direction in the angular distribution.

In summary, the ALP distributions from the two production processes have different features:

\[
e^+e^- \rightarrow a\gamma : \quad (\beta\gamma)_a \approx E/m_a \approx 400 \quad \text{(central)} \tag{2.10}
e^+e^- \rightarrow (a\gamma)\gamma : \quad 60 \lesssim (\beta\gamma)_a \lesssim 400 \quad \text{(forward)}.
\]

From these considerations it becomes clear that the number of ALP decays within a detector with limited angular coverage and thickness depends significantly on the production kinematics and the placement of the detector with respect to the production point.
3 Far detector options

The detection of a long-lived particle crucially depends on its decay probability at a distance from the production point. In this section, we review how the decay probability scales with the geometry and the position of a detector. Based on these considerations, we design three realistic far detectors at the ILC and compare their expected acceptance with the proposed main detector ILD.

Decay probability The probability for a particle $a$, produced in the direction $\vec{r}_a$ with decay length $d_a$, to decay within a distance $r \in [r_a^{\text{in}}, r_a^{\text{out}}]$ from its production point is given by

$$P_a(d_a; \vec{r}_a) = \exp\left(-\frac{r_a^{\text{in}}}{d_a}\right) - \exp\left(-\frac{r_a^{\text{out}}}{d_a}\right).$$

In practice, $r_a^{\text{in}}$ and $r_a^{\text{out}}$ are the positions at which the particle’s trajectory intersects with the detector boundaries. For a sample of $N$ particles, the average decay probability is
obtained as
\[ \langle P \rangle = \frac{1}{N} \sum_{a=1}^{N} P_a (d_a; \vec{r}_a). \] (3.2)

For particles with very long decay lengths, the average decay probability can be approximated by
\[ \langle d \rangle \gg r_{\text{in}}, \langle r \rangle : \quad \langle P \rangle \approx \frac{\Omega}{4\pi} \frac{\langle r \rangle}{\langle d \rangle}, \] (3.3)

where \( \Omega \) is the solid angle covered by the detector, \( \langle r \rangle \) is the average radial thickness of the detector, and \( \langle d \rangle \) is the particle's decay length averaged over its boost. As long as the kinematic distribution is sufficiently isotropic, the probability of very long-lived and/or highly boosted particles to decay inside the detector scales linearly with the detector dimensions \( \Omega \cdot \langle r \rangle \). Below we will use \( \Omega \cdot \langle r \rangle \) as a measure of acceptance when we consider different detector geometries.

At the ILC, we calculate the number of particles \( a \) that decay within a certain detector volume as
\[ N_a = L \frac{1}{N} \sum_{a=1}^{N} \sigma (e^+e^- \rightarrow a (d_a; \vec{r}_a) X) P_a (d_a; \vec{r}_a) \approx L \sigma (e^+e^- \rightarrow aX) \langle P \rangle. \] (3.4)

Here \( L \) is the integrated luminosity, set to \( L = 250 \text{fb}^{-1} \) in our analysis.

**Near and far detectors**

Two concepts for near detectors at the ILC have been developed, named ILD and SiD [23, 24]. We focus on the ILD, which is designed to be bigger and a priori more sensitive to particle decays away from the \( e^+e^- \) collision point. For our numerical analysis, we consider two parts of the detector that are well suited to reconstruct displaced vertices of charged particles: the multi-layer pixel vertex detector (VTX), which promises a high-precision vertex reconstruction, and the time projection chamber (TPC), which allows for tracking and timing over a larger volume. Taken together, the VTX and TPC parts of the ILD form a cylindrical decay volume for LLPs centered around the \( e^+e^- \) collision point, with

- **ILD:** \( z \in [-235, 235] \text{ cm}, \quad \rho \in [0.6, 180.8] \text{ cm}, \quad \theta \in [8, 172]^{\circ}. \)

Here \( z \) is the \( e^- \) beam direction, \( \rho \) is the radial distance from the beam axis, and \( \theta \) is the polar angle around the beam. The ILD has an excellent angular coverage, so that almost all LLPs decaying within the cylindrical shell with \( \rho \in [0.6, 180.8] \text{ cm} \) can be detected.

In addition to the ILD, we consider three options for far detectors that could be installed in planned underground cavities around the ILC detector hall or on the ground. One possible site is the vertical shaft above the collision point, which will be used to lower the main ILD and SiD detectors into the detector hall. A second possibility is to place a far detector inside the access tunnel that surrounds the detector hall. As a third option, we consider a large detector placed on the ground above the detector hall. We label these detectors Shaft, Tunnel and Ground, respectively, and design them with the following dimensions:
Figure 3: Far detector options around the ILC interaction point (IP) at \((x, y, z) = (0, 0, 0)\). Shown are a side view (top) and top view (bottom) of the projected far detectors in the Shaft (S, green), in the Tunnel (T, red), and on the Ground (G, orange), as well as the main detector ILD (blue). The Ground detector is centered around \((x, z) = (0, 0)\) and is too large to appear in the top view.

- Shaft (S): \(18 \times 30 \times 18\) m, centered around \((0, 45, 0)\) m
- Tunnel (T): \(140 \times 10 \times 10\) m, centered around \((0, -5, -35)\) m
- Ground (G): \(1000 \times 10 \times 1000\) m, centered around \((0, 75, 0)\) m.

The positioning \((x, y, z)\) of the detectors in the reference frame around the \(e^+e^-\) interaction point is illustrated in Fig. 3. As suggested by (3.3), the detector acceptance for long-lived particles is determined by the product of angular coverage and average radial thickness,
### Table 1: Geometric properties of the ILD and the three projected far detectors Ground, Shaft, and Tunnel: angular coverage $\Omega/(4\pi)$; average radial thickness $\langle r \rangle$; and measure of acceptance $\Omega \cdot \langle r \rangle$.

|                  | ILD | Ground | Shaft | Tunnel |
|------------------|-----|--------|-------|--------|
| $\Omega/(4\pi)$  | 0.999 | 0.44  | 0.026 | 0.046  |
| $\langle r \rangle$ [m] | 2.2  | 23    | 16   | 11     |
| $\Omega \cdot \langle r \rangle$ [sr m] | 27   | 126   | 5    | 6      |

In Tab. 1, we summarize these properties for the four proposed detector geometries. Based on the measure of acceptance, $\Omega \cdot \langle r \rangle$, we expect that the ILD will detect larger numbers of long-lived particles compared to the Shaft and Tunnel detectors, which suffer from a small angular coverage. With the Ground detector option, the acceptance increases by roughly a factor of 4 compared to the ILD. This is due to the huge size of the Ground detector, which compensates for the loss in angular coverage at a large distance from the collision point. Notice that these considerations apply for isotropically produced particles. For particles emitted mostly perpendicular to the beam line, the fraction of detected events at all three far detectors increases. At the ILD, in turn, the detection rate depends little on the angular distribution, due to the almost perfect angular coverage.

### 4 ILC discovery potential

Based on the results of Sections 2 and 3, we determine the reach of the three proposed far detectors for long-lived ALPs and compare it with the ILD. To this end, we have simulated 100 k events for each of the processes $e^+ e^- \rightarrow a\gamma$ and $e^+ e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$ with unpolarized initial leptons, using MadGraph5_aMC@NLO [25, 26]. With these samples, we then analyze the sensitivity of all four detectors to long-lived ALPs using our own analysis framework written in Python [27] and Jupyter [28].

**Theoretical sensitivity to long-lived ALPs** In Fig. 4, we show the expected number of ALPs, $N_a$, as defined in (3.4), for the ILD (blue), as well as the far detectors Shaft (green), Tunnel (red), and Ground (orange). We display the event rates as a function of the coupling $c_{\ell \ell}/f_a$ which determines the ALP’s decay width (2.8), for fixed $c_{WW}/f_a = 1$/TeV. Going from larger to smaller couplings $c_{\ell \ell}/f_a$, the event rates in all detectors increase exponentially as $\langle P \rangle \sim \exp(-r_{\text{in}}(c_{\ell \ell}/f_a)^2)$ and eventually drop as $\langle P \rangle \sim \langle r \rangle(c_{\ell \ell}/f_a)^2$, see (3.1) and (3.3). For the ILD, the event rate reaches its maximum at larger values of $c_{\ell \ell}/f_a$, i.e., at smaller decay lengths $\langle d \rangle \sim (c_{\ell \ell}/f_a)^{-2}$ than for the far detectors, because the ILD is located closer to the production point. Moreover, the ILD curve features a plateau around $r_{\text{in}} < \langle d \rangle < \langle r \rangle$, which is not observed for the far detectors. Indeed, the

---

5We calculate $\langle r \rangle$ as the arithmetic mean of the distances $r_{\text{out}} - r_{\text{in}}$ in a large sample of $N$ particle trajectories that intersect the detector volume, $\langle r \rangle = N^{-1}\sum_{a=1}^{N}(r_{\text{out}}^{a} - r_{\text{in}}^{a})$. 

- 8 -
Figure 4: Number of ALPs, $N_a$, decaying within various ILC detectors, as a function of the effective coupling to leptons, $c_{\ell\ell}/f_a$, fixing $c_{WW}/f_a = 1/\text{TeV}$ and $m_a = 300\text{ MeV}$. The event rates correspond to the production channels $e^+e^{-} \rightarrow a\gamma$ (left) and $e^+e^{-} \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$ (right) at $\sqrt{s} = 250\text{ GeV}$ and with $\mathcal{L} = 250\text{ fb}^{-1}$. Shown are predictions for the ILD (blue) and far detectors placed on the Ground (orange), in the Shaft (green), and in the Tunnel (red).

ILD is thick compared to its distance from the production point, $\langle r \rangle \gg r_{\text{in}}$, so that the exponential increase of the event rate with $\langle d \rangle$ saturates before it decreases at large decay lengths. For a thinner detector at the same location or for the same detector located further away from the production point, the plateau becomes less broad and eventually disappears. This is the case for the far detectors, where $\langle r \rangle \lesssim r_{\text{in}}$ and the event rates peak around $\langle d \rangle \gg r_{\text{in}}$, see also Ref. [18].

Besides the detector position and geometry, the absolute event rate also depends on the production cross sections from (2.6). For a specific production process, the predicted rate for the ILD is much larger than at the far detectors, except for ALPs with small couplings or long lifetimes. Moreover, for the ILD the shape of the distribution is largely process-independent. Both features are due to the excellent angular coverage of the ILD around the production point. In turn, at the far detectors the sensitivity to ALPs with different lifetimes depends on the production kinematics. In particular, ALPs from $e^+e^- \rightarrow (a\gamma)\gamma$ are boosted along the beam direction, see Fig. 2. Since the event rates depend on the ratio of boost and coupling, $d \sim (\beta\gamma)_a(c_{\ell\ell}/f_a)^{-2}$, a larger boost is compensated by a larger coupling and vice versa. This effect leads to enhanced event rates at large couplings for the Tunnel detector (placed in the beam direction) and reduced rates at the Shaft detector (located centrally and perpendicular to the beam).

To illustrate the expected sensitivity to an ALP signal, in Fig. 4 we indicate event rates of $N_a = 3$ as horizontal dashed lines. In the ideal case of zero background, the observation of 3 events would correspond to excluding the no-signal hypothesis at 95% CL, assuming Poisson statistics and 100% reconstruction efficiency. Of course, such a scenario is unrealistic, but it allows us to compare the sensitivity of the respective detectors, assuming that
Table 2: Expected sensitivity to the ALP coupling to leptons, $c_{\ell\ell}/f_a$, for two production processes with fixed $c_{WW}/f_a = 1/\text{TeV}$, at the ILD and the three far detectors. The values correspond to observing $N_a = 3$ signal events from an ALP with mass $m_a = 300 \text{ MeV}$ in an ideal experiment with zero background, which would exclude the no-signal hypothesis at the 95\% CL. Small couplings $c_{\ell\ell}/f_a$ indicate a high sensitivity to ALPs with long lifetimes.

| $c_{\ell\ell}/f_a \ [10^{-4}/\text{TeV}]$ | ILD | Ground | Shaft | Tunnel |
|-----------------------------------------|-----|--------|-------|--------|
| $e^+e^- \rightarrow a\gamma$           | 1.3 | 0.58   | 3.1   | 2.4    |
| $e^+e^- \rightarrow (a\gamma)\gamma$  | 1.2 | 0.54   | 3.0   | 2.2    |

The background rate and reconstruction efficiency is similar for all detectors. In Tab. 2, we show the smallest ALP couplings $c_{\ell\ell}/f_a$ that can be probed at the ILD and at the far detectors. Smaller couplings imply a higher sensitivity to long-lived ALPs. The Ground detector can improve the sensitivity by a factor 2 compared to the ILD. However, the improvement is much smaller than naively expected from the acceptance measures in Tab. 1. The reason is that the approximation $\langle P \rangle \sim \Omega \cdot \langle r \rangle$ from (3.3) does not apply for the ILD, because the condition $\langle d \rangle \gg \langle r \rangle$ in (3.3) is not fulfilled for the processes we consider. The Shaft and Tunnel detectors collect smaller event rates than the ILD. They might only be useful additions in the case of better background rejection or higher reconstruction efficiency than at the ILD.

Generalization For a less model-dependent interpretation of these results, in Fig. 5 we show contours of $N_a = 3$ as a function of the production cross section $\sigma$ and the proper lifetime $c\tau_a$ of the ALP. An ideal ILC experiment would probe the area above these...
Figure 6: Event rates $N_a$ of ALPs with $m_a = 300$ MeV decaying within the ILD, as a function of the production cross section, $\sigma$, and the proper lifetime, $c\tau_a$. Shown are the production channels $e^+e^- \to a\gamma$ (left) and $e^+e^- \to Z\gamma \to (a\gamma)\gamma$ (right) at $\sqrt{s} = 250$ GeV and with $L = 250$ fb$^{-1}$.

contours. Since these results only depend on the production kinematics and the lifetime of the ALP, any (pseudo-)scalar particles with flavor-hierarchical couplings and masses well below the weak scale should lead to very similar results. This allows us to conclude more generally that only far detectors with a very large geometric acceptance $\Omega \cdot \langle r \rangle$ can improve the sensitivity to such LLPs, provided that the production cross section is large enough to probe particles with lifetimes beyond the reach of the ILD.

Experimental sensitivity In our estimates, we have assumed that every ALP that decays inside the detector is reconstructed. In reality, however, the reconstruction of a displaced vertex of charged tracks from $a \to \ell^+\ell^-$ decays depends on the track length, angular separation and boost of the charged particles. The effective detection volume is thus smaller than the detector acceptance. This effect is particularly important for detectors that are relatively thin and far away from the production point, where the decay probability is proportional to the thickness, $\langle P \rangle \sim \langle r \rangle$.

To illustrate the dependence of the sensitivity on the event rates, in Fig. 6 we show the predicted number of ALPs decaying within the ILD as a function of the production cross section and lifetime. The event rate decreases proportionally with the cross section and anti-proportionally with the lifetime in the limit of long decay lengths, as expected from (3.4) and (3.3).

The signal sensitivity is also expected to be reduced in the presence of background. At hadron colliders, the dominant source of background for displaced charged vertices are meson decays. At the ILC, mesons are produced at comparably lower, but still substantial rates, for example from hadronic $Z$ boson decays. Further background sources could be misreconstructed muon decays originating from $e^+e^-$ collisions or from cosmic rays. Ideas to tame such and other backgrounds have been discussed for Belle II in Ref. [29]. Notice
that background can affect not only the absolute, but also the relative sensitivity of the various detectors. A dedicated background analysis goes beyond the scope of this work, but is crucial to determine the ultimate sensitivity of the ILC to long-lived particles.

5 ILC versus Belle II

Long-lived particles with masses below a few GeV could well be observed at flavor experiments. ALPs produced through gauge interactions and decaying into leptons can be efficiently searched for in meson decays $B \rightarrow Ka, a \rightarrow \mu^+ \mu^-$ or $K \rightarrow \pi a, a \rightarrow \mu^+ \mu^-$. In these decays, the ALP can be reconstructed from a prompt or displaced vertex, depending on its lifetime. At $e^+ e^-$ experiments, ALPs could also be produced directly via $e^+ e^- \rightarrow \gamma a, a \rightarrow \ell^+ \ell^-$, resulting in a signature of a displaced vertex and a prompt photon. This signature has recently been explored for a similar scenario with dark photons at Belle II and found to probe very small couplings \[30\]. An interpretation for ALPs would be a worthwhile endeavor, but goes beyond the scope of this work.

ALPs in meson decays The currently strongest bounds on long-lived ALPs in $B \rightarrow Ka, a \rightarrow \mu^+ \mu^-$ have been obtained by the LHCb collaboration \[31\]. The Belle II experiment can search for these decays in $e^+ e^-$ collisions at the $\Upsilon(4S)$ resonance $\sqrt{s} = 10.58$ GeV and potentially extend the reach for long-lived light pseudo-scalars \[32–34\]. It is thus interesting to compare the projected sensitivity for Belle II with our predictions for the ILC. While both experiments rely on electron-positron collisions, they probe ALPs in different production channels and phase-space regions.

For ALPs with coupling $c_{WW}$, the decay $B \rightarrow Ka$ is induced by flavor-changing neutral currents at one-loop level, as illustrated in Fig. 7. At energies $\mu < \mu_w$ below the weak scale, the ALP coupling to left-handed bottom and strange quarks is described by a local operator in the effective Lagrangian

$$L_{\text{eff}}(\mu < \mu_w) \supset C_{sb}(\mu) \frac{\partial^\mu a}{f_a}(\bar{s}_L \gamma^\mu b_L) + \text{h.c.}$$ (5.1)
At the weak scale $\mu_w \approx m_W$, the Wilson coefficient reads

$$C_{sb}(\mu_w) = -V_{ts}^* V_{tb} \frac{\alpha_t}{4\pi} \frac{3\alpha}{2\pi^2 s_w^2} \frac{1 - x_t + x_t \ln x_t}{(1 - x_t)^2} c_{WW}(\mu_w), \quad (5.2)$$

where $\alpha_t = y_t^2/4\pi$ and $x_t = m_t^2/m_W^2$. The evolution down to the bottom mass scale $m_b$ can be neglected, so that $C_{sb}(\mu_w) \approx C_{sb}(m_b)$ [35]. The decay rate is finally given by

$$\Gamma(B \to Ka) = \frac{m_B}{16\pi} \left( \frac{C_{sb}(m_b)}{f_a} \right)^2 f_0^2(m_a^2) \left( 1 - \frac{m_K^2}{m_B^2} \right)^2 \lambda^{1/2}(m_B^2, m_K^2, m_a^2), \quad (5.3)$$

with the kinematic function $\lambda(a, b, c) = a^2 + b^2 + c^2 - 2(ab + ac + bc)$ and the $B \to K$ scalar form factor $f_0(q^2)$ at momentum transfer $q^2 = m_a^2$ [36].

**Belle II’s sensitivity to long-lived ALPs** To determine the expected event rates for $B^+ \to K^+ a, a \to \mu^+ \mu^-$, we closely follow the analysis of Ref. [29]. Based on a sample of 10,000 simulated events, we determine the number of ALPs that decay within the Belle II tracking detector as

$$N_a = N_{BB} B(B \to Ka) B(a \to \mu^+ \mu^-) \langle P \rangle. \quad (5.4)$$

Here $N_{BB} = 5 \cdot 10^{10}$ is the number of $B \bar{B}$ pairs expected at Belle II for an integrated luminosity of 50 ab$^{-1}$ and $\langle P \rangle$ is the average probability for an ALP to decay within the Belle II detector volume. We consider only the tracking parts of the Belle II detector, i.e., the PXD, SVD, and CDC, which feature a good reconstruction efficiency for displaced vertices [20]. Furthermore, we reduce the outer radius of the CDC from 113 cm to 60 cm, in order to allow for long enough tracks that can be reconstructed with less detector resolution than in the PXD and SVD. The resulting effective detection volume is defined as

- Belle II: $z \in [-55, 140]$ cm, $\rho \in [0.9, 60]$ cm, $\theta \in [17, 150]^\circ$,

with the electron beam pointing along the positive $z$ direction and the $e^+ e^-$ collision point placed at $(z, \rho) = (0, 0)$.

In Fig. 8, we show a contour of $N_a = 3$ ALP decays as expected from $B^+ \to K^+ a, a \to \mu^+ \mu^-$ decays at Belle II for 50 ab$^{-1}$ of data. The area above the contour can be probed with meson decays. The results are shown for an ALP mass $m_a = 300$ MeV and as a function of the ALP couplings $c_{WW}$ and $c_{\ell\ell}$. From (5.2) and (5.3), it is apparent that the production rate of the ALPs scales as $\mathcal{B}(B \to Ka) \sim (c_{WW}/f_a)^2$. We have assume that the ALP decays always into muons and have set the branching ratio to $\mathcal{B}(a \to \mu^+ \mu^-) = 1$, as for the ILC analysis. The event rate $N_a$ thus depends on the lepton coupling only through the lifetime, yielding $\langle P \rangle \sim (c_{\ell\ell}/f_a)^2$ for large decay lengths or small couplings, see (3.3). In this parameter region, the event rate scales as $N_a \sim (c_{WW} c_{\ell\ell}/f_a^2)^2$, resulting in a straight line on the double-logarithmic scale.

---

We thank Torben Ferber for sharing his event samples with us.

We have not made such a request for the ILC detectors, which leads to a slight bias in the comparison with Belle II.
Figure 8: Sensitivity projections for long-lived ALPs with $m_a = 300$ MeV at the ILC and at Belle II, as a function of the couplings $c_{WW}/f_a$ and $c_{ll}/f_a$. Shown are $N_a = 3$ contours for ALP decays within the ILD for $e^+e^- ightarrow a\gamma$ (blue) and $e^+e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$ (red) production at $\sqrt{s} = 250$ GeV and with $L = 250$ fb$^{-1}$. For comparison, $N_a = 3$ contours are shown for $B^+ \rightarrow K^+ a$, $a \rightarrow \mu^+\mu^-$ decays within the tracking chambers of the Belle II detector with $L = 50$ ab$^{-1}$. Sensitivity at Belle II versus ILC  

For comparison, in Fig. 8 we also show the expected reach of the ILD for ALPs produced via $e^+e^- \rightarrow a\gamma$ and $e^+e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$. For decay lengths $\langle d \rangle \gg 2$ m, the event rate (3.4) scales with the couplings as $N_a \sim (c_{WW}c_{ll}/f_a^2)^2$, as for meson decays. In our benchmark scenario with $m_a = 300$ MeV and $c_{ll}/f_a \ll 1$/TeV, we find $N_a = 3$ events for

\begin{align}
\text{Belle II } B^+ \rightarrow K^+ a: & \quad |c_{WW}c_{ll}/f_a^2| = 2.0 \cdot 10^{-4}/\text{TeV}^2 \\
\text{ILD } e^+e^- \rightarrow a\gamma: & \quad |c_{WW}c_{ll}/f_a^2| = 1.24 \cdot 10^{-4}/\text{TeV}^2 \\
\text{ILD } e^+e^- \rightarrow (a\gamma)\gamma: & \quad |c_{WW}c_{ll}/f_a^2| = 1.17 \cdot 10^{-4}/\text{TeV}^2,
\end{align}

assuming luminosities of 50 ab$^{-1}$ for Belle II and 250 fb$^{-1}$ for the ILC. In Fig. 8, these values define the straight lines at small $c_{ll}/f_a$. At the ILD, the expected sensitivity to small couplings is thus improved by about 60% compared with Belle II. More generally, the ILD will be more sensitive to long-lived ALPs than Belle II throughout the parameter space. The gain is particularly large at small $c_{WW}$, due to the larger production rates and the excellent detector coverage around the ILC interaction point. For $e^+e^- \rightarrow a\gamma$, the sensitivity at small $c_{WW}$ is larger than for $e^+e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$, due to the larger cross section (2.6).

From the positions of the minima along the contours, we deduce that the ILD is most sensitive at larger $c_{ll}$ or shorter lifetimes compared to Belle II, due to the higher boost of the ALPs at the ILC. At very short lifetimes, both Belle II and the ILC can efficiently search for promptly decaying particles and complement the reach of displaced vertex searches, see for instance [34, 37, 38].
6 Conclusions

In this work we have addressed the question whether near or far detectors are more sensitive to long-lived particles produced at future electron-positron colliders. We have performed a comparative study for sub-GeV axion-like particles produced via $e^+e^- \rightarrow a\gamma$ and $e^+e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$ at the ILC. The two production channels lead to different kinematic distributions: ALPs from $e^+e^- \rightarrow a\gamma$ are emitted mostly perpendicular to the beam axis, while ALPs from $Z$ boson decays in $e^+e^- \rightarrow Z\gamma \rightarrow (a\gamma)\gamma$ are boosted along the beam axis. These kinematics affect the relative sensitivity of detectors placed in the forward direction or in the central region. We have demonstrated this effect for two realistic far detector options, one placed in a supply tunnel in the forward region and one placed in a vertical shaft above the ILC interaction point.

Neither of these underground far detectors can enhance the sensitivity to LLPs compared to the main detector ILD. This is mostly due to the almost full angular coverage and relative thickness of the ILD, which captures a large number of particles with decay lengths beyond its geometric extensions. To enhance the sensitivity to LLPs, any far detector must have a large angular coverage and a larger radial thickness than the ILD. For an underground experiment, such conditions can realistically only be fulfilled on the ground. With a kilometer-sized cuboid on the surface above the ILC detector hall the sensitivity to long lifetimes increases by about a factor of four. Moderate improvements with far detectors thus require a substantial extra construction effort.

A key result of our analysis is that the ILC main detector itself is very sensitive to long-lived particles. For light pseudo-scalars produced at picobarn rates, the ILD can probe decay lengths up to 100 m with a luminosity of 250 fb$^{-1}$. For smaller cross sections in the femtobarn range, the sensitivity still reaches decay lengths of about 10 cm.

To quantify the gain of a high-energy lepton collider over current low-energy experiments, we have compared our predictions for the ILC with searches for long-lived ALPs produced from meson decays at Belle II. At long lifetimes, the ILC can improve the sensitivity to the product of ALP couplings, $c_{WW}c_{\ell\ell}/f_a^2$, by about 60% compared to Belle II. At shorter lifetimes, where the ILC reaches its maximum sensitivity, the ILD can probe ALPs produced through couplings $c_{WW}$ that are an order of magnitude smaller than the reach of Belle II with its total expected luminosity of 50 ab$^{-1}$.

These results apply more generally for ALPs that are effectively massless at the ILC, i.e., particles with masses below a few GeV, provided that the lifetime is rescaled accordingly. Heavier ALPs are produced with tendentially lower boosts and have shorter lifetimes. Both features lead to enhanced event rates in near detectors. We expect similar results for other LLPs produced through weak interactions and with comparable lifetimes.

All our statements are based on pure event rates, assuming a perfect detector with zero background and excellent reconstruction efficiency. Realistic predictions of the ultimate sensitivity require a dedicated analysis of background and detector effects, which goes
beyond the scope of this study. However, our predictions for the ILC under ideal conditions allow for a better comparison with other electron-positron colliders. For similar collision energies, the main messages from this work should apply as well to the FCC-ee and CEPC. They can serve as a guideline to optimize the LLP program at the next high-energy collider.

Acknowledgments

We thank Hitoshi Murayama and Maxim Perelstein for their enthusiasm for this study and for interesting discussions. We also thank Torben Ferber for providing us with event simulations for Belle II and for helpful discussions.
