Abstract

We present 20 years of seawater inorganic carbon measurements collected along the western shelf and slope of the Antarctic Peninsula. Water column observations from summertime cruises and seasonal surface underway pCO$_2$ measurements provide unique insights into the spatial, seasonal and interannual variability of this dynamic system. Discrete measurements from depths >2000 m align well with World Ocean Circulation Experiment observations across the time-series and underline the consistency of the data set. Surface total alkalinity and dissolved inorganic carbon data showed large spatial gradients, with a concomitant wide range of $\Omega_{\text{arag}}$ (< 1 up to 3.9). This spatial variability was mainly driven by increasing influence of biological productivity towards the southern end of the sampling grid and melt water input along the coast towards the northern end. Large inorganic carbon drawdown through biological production in summer caused high near-shore $\Omega_{\text{arag}}$ despite glacial and sea-ice melt water input. In support of previous studies, we observed Redfield behavior of regional C/N nutrient utilization, while the C/P (80.5 ± 2.5) and N/P (11.7 ± 0.3) molar ratios were significantly lower than the Redfield elemental stoichiometric values. Seasonal salinity-based predictions of $\Omega_{\text{arag}}$ suggest that surface waters remained mostly supersaturated with regard to aragonite throughout the study. However, more than 20% of the predictions for winters and springs between 1999 and 2013 resulted in $\Omega_{\text{arag}} < 1.2$. Such low levels of $\Omega_{\text{arag}}$ may have implications for important organisms such as pteropods. Even though we did not detect any statistically significant long-term trends, the combination of ongoing ocean acidification and freshwater input may soon induce more unfavorable conditions than the ecosystem experiences today.
1 Introduction

Antarctic continental shelves are viewed as strong anthropogenic CO$_2$ sinks and therefore play an important role in global biogeochemical cycles [Arrigo et al., 2008]. These highly productive regions also support ecosystems that are exposed to rapid environmental change [Ducklow et al., 2007, 2012]. Conditions along the western shelf of the Antarctic Peninsula (WAP, Figure 1) are characterized by rapid ocean-atmosphere warming, sea-ice retreat and melting of glaciers [Ducklow et al., 2012; Stammerjohn et al., 2012; Meredith et al., 2013], impacting phytoplankton concentrations [Montes-Hugo et al., 2009] and higher trophic level organisms such as krill, fish, and Adélie Penguins [Ducklow et al., 2007, 2012; Schofield et al., 2010]. Climate and oceanographic trends are also mirrored in the inorganic carbon dynamics, which could feed back to global carbon cycling and/or enhance the projected fast progression of Southern Ocean acidification [McNeil and Matear, 2008; Steinacher et al., 2009; Bopp et al., 2013], thereby imposing additional environmental stressors on the ecosystem.

In the WAP, carbon biogeochemistry is controlled by an interplay of physical and biological mechanisms, which include photosynthesis, respiration, freshwater input, gas exchange, sea-ice cover, winds, and horizontal advection [Carrillo and Karl, 1999; Carrillo et al., 2004; Wang et al., 2009; Montes-Hugo et al., 2010]. The physical oceanography of the region is strongly influenced by equatorward flow at the continental shelf/slope break associated with the eastward flowing Antarctic Circumpolar Current that abuts the continental slope along the WAP region. On the shelf, there are indications of one or more cyclonic circulation cells with poleward flow inshore [Hofmann et al., 1996; Dinniman and Klinck, 2004; Martinson et al., 2008]. Water mass properties are strongly influenced by subsurface intrusions onto the continental shelf of warm, nutrient and DIC rich Upper Circumpolar Deep Water (UCDW), that appears to be modulated by topographic depressions and canyons [Martinson et al. 2008; Dinniman et al., 2011; Martinson and McKee, 2012]. In winter, respiration processes and the entrained deep CO$_2$-rich water increase the DIC concentration in surface waters to supersaturated levels of CO$_2$ with respect to the atmosphere [Carrillo et al., 2004; Wang et al., 2009; Tortell et al., 2014; Legge et al., 2015]. From austral spring through summer, sea-ice retreats from north to south and from offshore to inshore [Smith and Stammerjohn, 2001]. If not
counteracted by strong winds, freshwater from melting sea-ice, glaciers and snow. Meredith et al., 2013] stabilizes the water column in close proximity to the inshore and southward moving sea-ice edge. Stratification and presumably iron availability provide favorable conditions for phytoplankton blooms [Garibotti et al., 2003, 2005; Vernet et al., 2008], resulting in a strong drawdown of dissolved inorganic carbon (DIC) and flux of CO$_2$ from the atmosphere into the ocean [Carrillo et al., 2004; Montes-Hugo et al., 2009; Wang et al., 2009]. Subsequent iron depletion results in a decreasing trend of chlorophyll $a$ (Chl $a$) from onshore to offshore, with interannual differences in the gradient strength, depending on the onset of the sea-ice retreat [Garibotti, 2005; Garibotti et al., 2005], but possibly also the timing of sampling in relation to the timing of sea ice retreat and phytoplankton blooms.

The inorganic carbon dynamics are further complicated by large-scale atmospheric patterns. The El Niño Southern Oscillation (ENSO) and Southern Annular Mode (SAM) drive the WAP climate and oceanography on interannual to multidecadal timescales [Yuan and Martinson, 2001; Stammerjohn et al., 2008a]. During La Niña years, storms become longer and more intense, temperatures increase and sea ice extent decreases in the WAP region as a result of a strong low-pressure system driven by the poleward displacement of the polar jet [Yuan, 2004]. Positive SAM phases are also associated with positive temperature anomalies over the Antarctic Peninsula and decreased sea-ice extent [Kwok, 2002; Stammerjohn et al., 2008]. Furthermore, the SAM brings the Southern Hemisphere westerly winds closer to Antarctica, which amplifies the typical features of La Niña. During these periods, nutrient and CO$_2$-rich Circumpolar Deep Water intrudes more frequently on to the shelf [Martinson et al., 2008], potentially increasing [CO$_2$] on the shelf. On the other hand, weaker and fewer storms and spatial and temporal extension of sea-ice coverage are observed in negative phases of SAM, with associated stronger stratification of the water column and enhanced biological productivity [Saba et al., 2014]. These features are further intensified when a negative SAM coincides with El Niño [Stammerjohn et al., 2008b].

The WAP oceanography and ecosystem have been intensely observed as part of the PAL-LTER (Palmer Long Term Ecological Research) program (http://pal.lternet.edu/) over the past two decades [Ducklow et al., 2007, 2012]. Since
this multifaceted data set also contains seawater inorganic carbon measurements taken each January along transects shown in Figure 1. We complement the summertime inorganic carbon measurements from PAL-LTER with surface underway pCO₂ measurements that cover all four seasons [Takahashi et al., 2015]. Here, we describe the spatial, seasonal and interannual variability of the inorganic carbon system over the past two decades with the intention to improve our understanding of the main physical and biological controls. Furthermore, such a uniquely long data set allows us to gain first insights into the impacts of ocean acidification on the region.

2 Data and Methods

2.1 In situ data and calculation of carbonate system variables

We used discrete measurements of seawater DIC, total alkalinity (TA) and nutrients collected during ship-based cruises as part of the PAL-LTER program, along with temperature and salinity from CTD casts. The data were gathered along the PAL-LTER sampling grid (Figure 1), which runs 500 km along the coast and 250 km across the shelf. The along shelf transects were spaced every 100 km, with 20 km between the stations. The data were collected on an annual summertime cruise each January - February from 1993 through 2012. Carbon system sample collection and analysis were performed by David Karl and Chris Carrillo for data prior to 2003, and by Hugh Ducklow and Matthew Erickson for data from 2003 onward, with the exception that DIC analysis was done by Taro Takahashi in 2003 and 2004. No TA data were collected during 2003-2004.

Following the WOCE-JGOFS protocols, discrete samples of DIC and TA (300 ml) from Niskin bottle casts were preserved with 200 µl saturated HgCl₂ solution and sealed [Dickson and Goyet, 1994]. DIC was analyzed by coulometric determination of extracted CO₂ [Johnson et al., 1987]. TA was measured with the potentiometric titration method. Certified Reference Materials (provided by A.G. Dickson, Scripps Institution of Oceanography) were used to assure internal consistency of data with a precision of ± 2 µmol kg⁻¹ for DIC and ± 5 µmol kg⁻¹ for TA. Water for inorganic nutrient analysis was subsampled from Niskin bottles into acid washed 50 mL Falcon tubes and frozen at -70 °C. The samples were first analyzed using a Lachat Quickchem 8000 autoanalyzer at the University of California at Santa Barbara Marine Science Institute Analytical Lab (1993-
2007) and later at the Marine Biological Laboratory (Woods Hole MA, 2008 – 2012). Inorganic nutrient data reach a precision of ± 1 %. All PAL-LTER data and a detailed description of the sampling methodology are publicly available at http://pal.lternet.edu/ (dissolved inorganic nutrients, PAL-LTER dataset 27).

Calculated pH and saturation state for aragonite ($\Omega_{arag}$) were determined from DIC, TA, temperature, salinity, phosphate, silicate and pressure using the CO2SYS MATLAB-version [van Heuven et al., 2011]. To determine the carbonate variables we applied the dissociation constants for carbonic acid by Dickson and Millero, [1987] (refit from Mehrbach et al., [1973]). The CO$_2$ solubility equations of Weiss, [1974], and dissociation constants for boric acid by Dickson, [1990] were also used to determine pH and $\Omega_{arag}$. pH is reported on the total H$^+$ ion concentration scale (pHT).

The Lamont-Doherty Earth Observatory (LDEO) measured underway-surface pCO$_2$ with a precision of ± 0.5 %, together with salinity and temperature in various seasons between 1999 and 2013, using a shower-type water-gas equilibrator and infrared CO$_2$ gas analyzer (see www.ldeo.columbia.edu/pi/CO2 for the operational and engineering details [Takahashi et al., 2015]). A range of five standard gas mixtures spanning between 100 ppm and 700 ppm mole fraction CO$_2$ certified by the Earth System Research Laboratory of the National Oceanic and Atmospheric Administration (NOAA) was used to calibrate the system every four hours.

2.2 Comparison with deep-water WOCE/CLIVAR inorganic carbon system data

We checked the consistency of the PAL-LTER DIC and TA data by comparing PAL-LTER deep-water (> 2000 m), offshore TA and DIC measurements to deep-water data collected during the World Ocean Circulation Experiment (WOCE) and Climate and Ocean – Variability, Predictability, and Change (CLIVAR) cruises along parts of sections A21 and S4P that were overlapping with the PAL-LTER grid (data available at http://www.nodc.noaa.gov/woce/wdu/). The WOCE and CLIVAR shipboard measurements were calibrated using seawater certified reference materials (prepared by A. G. Dickson, Scripps Institute of Oceanography), leading to an estimated precision of ±2 $\mu$mol kg$^{-1}$. DIC was measured on all cruises. When necessary, TA was calculated from DIC and either fCO$_2$ or pCO$_2$ following the same procedure as described in Section
2.1. Figure 2a shows the stations along the WAP where deep-water samples were taken during PAL-LTER and WOCE cruises. PAL-LTER DIC and TA measurements were within the range of sampled/calculated DIC and TA from the WOCE and CLIVAR cruises, (Figures 2b and c). After removing five outliers, mean deep-water DIC ($\text{DIC}^{\text{mean}} = 2260.6 \pm 3.8 \, \mu\text{mol kg}^{-1}$) and TA ($\text{TA}^{\text{mean}} = 2365.4 \pm 7.0 \, \mu\text{mol kg}^{-1}$) from PAL-LTER cruises corresponded well with the data measured/calculated from WOCE cruises ($\text{DIC}^{\text{mean}} = 2261.8 \pm 3.0 \, \mu\text{mol kg}^{-1}$; $\text{TA}^{\text{mean}} = 2365.9 \pm 9.3 \, \mu\text{mol kg}^{-1}$).

2.3 Comparison with underway-surface pCO$_2$ data

We also undertook a quality check of the PAL-LTER discrete surface DIC and TA data (depth < 5 m) by comparing PAL-LTER pCO$_2$, which was calculated using observed DIC and TA values, to LDEO pCO$_2$. LDEO pCO$_2$ samples that were collected during the PAL-LTER cruises were spatially matched with the PAL-LTER derived pCO$_2$ values by choosing the nearest latitude and longitude pair within a 1 km distance. Four PAL-LTER pCO$_2$ outliers that underestimate/overestimate pCO$_2$ relative to the underway observations by more than 150 µatm were removed. Analysis of the corrected data set with a Linear Regression Type II model suggests a correlation of $r = 0.82$ (Figure A1, Table 1). Some of the observed discrepancies may be attributed to errors in matching the times of bottle samples with those of underway pCO$_2$ measurements. Seawater inorganic carbon chemistry is highly variable along the WAP due to the influence of productivity, respiration, freshwater and upwelling of CO$_2$-rich subsurface water [Carrillo et al., 2004]. Small matching errors may therefore introduce small DIC and TA offsets, which would translate into larger fractional differences in pCO$_2$ due to the large Revelle Factor ($\partial \ln \text{pCO}_2 / \partial \ln \text{DIC}$) common in the region [Sarmiento and Gruber, 2006].

3 Results

Here, we examine the observed spatial summer patterns of DIC, TA, pHT and $\Omega_{\text{arag}}$ along the WAP and explore the underlying biological and physical drivers. We then discuss regional carbon – nutrient drawdown ratios and present our seasonal $\Omega_{\text{arag}}$ predictions that give initial insights into the chemical environment in the more poorly sampled spring, fall
and winter months. Finally, using the LTER and LDEO data sets, we investigate temporal trends over the past two decades.

3.1 Spatial summertime patterns of the inorganic carbon system

Surface waters in the PAL-LTER region exhibited high spatial and interannual variability of DIC (min = 1850 µmol kg\(^{-1}\) and max = 2173 µmol kg\(^{-1}\)), TA (min = 2087 µmol kg\(^{-1}\) and max = 2396 µmol kg\(^{-1}\)), and salinity (min = 30.3 and max = 33.9) across the shelf. As a result, surface \(\Omega_{\text{arag}}\) reached levels as low as 0.98 in 1996, while maximum \(\Omega_{\text{arag}}\) values were > 3 in several years (Figure 3). Off-shore, DIC (min = 2072 µmol kg\(^{-1}\) and max = 2255 µmol kg\(^{-1}\)), TA (2265 µmol kg\(^{-1}\) and 2355 µmol kg\(^{-1}\)), and salinity (min = 33.4 and max = 34) were less variable, resulting in a smaller \(\Omega_{\text{arag}}\) range (min = 1.14 and max = 2.41). Additional aragonite undersaturation was detected between 100 and 200 m depth in 2005 and 2007 (Figure 3). At depths > 70 m, which is below the mixed layer depth, \(\Omega_{\text{arag}}\) was < 1.5 in all years.

To gain a spatial overview of the general summertime surface features (upper 5 m), we linearly interpolated the observations in space and averaged across years with available DIC and TA (or nutrient) measurements. Averages are only shown for regions where samples were taken in more than 5 years (Figure 4). The resulting \(pCO_2\), pH, \(\Omega_{\text{arag}}\), TA, salinity, DIC, and nutrient fields exhibited clear onshore – offshore gradients. With the exception of DIC, all variables also followed a north-south gradient. Mean summertime surface \(pCO_2\) was lowest (<200 µatm) in the southern coastal region and was about 60 to 70 µatm lower than in the northern near-shore regions (Figure 4a). The highest mean summertime \(pCO_2\) values were found in the northern slope region (300-325 µatm). The opposite pattern was reflected in \(\Omega_{\text{arag}}\) and pH, with highest values (\(\Omega_{\text{arag}}^{\text{max}}\) = 2.6 and pH\(\text{max}^{\text{max}}\) 8.3) close to the coast and south of 66.5°S (Figures 3b and c), decreasing along the coast towards the north to pH ~8.2 and \(\Omega_{\text{arag}} \sim 1.9\), and reaching the lowest levels in northern offshore waters (pH\(\text{min}^{\text{min}}\) = 8.1; \(\Omega_{\text{arag}}^{\text{min}}\) = 1.7). TA also exhibited north-south and onshore – offshore gradients, with values as low as 2185 µmol kg\(^{-1}\) in the northern near-shore regions and as high as > 2300 µmol kg\(^{-1}\) offshore. The low TA values along the northern part of the coast coincided with the lowest salinity values of 31.8, suggesting dilution of TA due to freshwater input (Figures 3d and e). Higher TA
values offshore were also reflected in increased DIC and salinity concentrations, with temperatures between 1.3 – 1.5 °C. DIC also exhibited an onshore–offshore gradient with values about 80 to 100 µmol kg\(^{-1}\) lower in the near shore region compared to offshore, but there was no significant north-south gradient despite the presence of freshwater in the north (Figure 4f). Salinity normalized DIC (sDIC, normalized with UCDW salinity = 34.7) was lowest in the southern region, thereby indicating that biological processes likely counteracted the expected north-south DIC gradient due to the pronounced freshwater influence on DIC in the north (Figure 4g).

3.2 Physical and biological drivers of the inorganic carbon system

In this section we examine the physical and biological mechanisms that control the observed variability in DIC and TA. DIC can decrease (increase) through dilution with freshwater (evaporation), organic matter production (remineralization), CO\(_2\) outgassing to the atmosphere (CO\(_2\) uptake) and/or precipitation of CaCO\(_3\) (dissolution). While positive net community production decreases DIC, the biological effect of organic matter production on TA depends on the source of nitrogen, where nitrate consumption increases TA and ammonium consumption decreases TA [Goldman and Brewer, 1980]. Since nitrate is more abundant than ammonium in WAP surface waters [Serebrennikova and Fanning, 2004], nitrate was assumed as the nitrogen source. With a Redfield stoichiometry of 6.6 mol C/mol N then TA should increase by \(1/6.6 = +0.15\) µmol TA per µmol DIC consumed. Precipitation of biological CaCO\(_3\) material reduces both DIC and TA with the effect on TA twice as large as that on DIC (2 µmol /µmol). TA is not affected by gas exchange but does vary as a result of dilution and evaporation.

Indications of surface reductions in TA and DIC due to freshwater input are evident along the WAP, and therefore freshwater processes (sea-ice and glacial melt, precipitation) [Meredith et al., 2013] appear to be important factors influencing the summertime carbon dynamics along the WAP. Figure 5 shows TA (circles) and DIC (diamonds) as a function of salinity. The black lines represent the dilution lines for TA and DIC, which were calculated following Yamamoto-Kawai et al., [2009]. UCDW end members are based on average TA and DIC concentrations in the water mass identified as
UCDW (black frames) [Martinson et al., 2008]. Upper-ocean TA follows its dilution line closely, with stronger positive deviations of about 35 µmol kg\(^{-1}\) on average. In contrast, DIC values fall considerably below the dilution line. A DIC drawdown of about 60 µmol kg\(^{-1}\) is visible in the winter water (grey diamonds), which increased to more than 200 µmol kg\(^{-1}\) in the mixed layer, leading to \(\Omega_{\text{arag}}\) as low as 1.5 and as high as 3.9.

The DIC drawdown relative to the salinity mixing-dilution line is most likely due to biological production of organic matter. Figure 6 shows sDIC as a function of salinity-normalized TA (sTA) for waters shallower than UCDW (orange dots). The regression line (solid black line, sTA = -0.11 x sDIC + 2601, RMSE = 18.6) ± 2σ (dashed lines) for estimated measurement precision (σ = +/- 5 µmol kg\(^{-1}\)) is similar to the nitrate-based photosynthesis line (blue line), indicating that the large decrease in DIC with the concomitant smaller increase in TA was mainly due to net biological production of organic matter. The photosynthesis line is based on winter water (WW) DIC and TA end-members (blue dots) and a slope of -1/6.2. According to the Redfield ratios (C/N/P = 106:16:1, [Redfield, 1958]), photosynthetic utilization of 1 mole of NO\(_3\) increases TA by 1 µmol kg\(^{-1}\) [Wolf-Gladrow et al., 2007] and decreases DIC by 106/16 (6.6). However, since the TA titration was performed to a pH of about 3, the TA values include residual PO\(_4\)-\(^3\), which leads to this slightly shallower slope of 6.2.

The intense, biologically driven DIC drawdown and resulting pCO\(_2\) undersaturation in the mixed layer may have led to some CO\(_2\) uptake from the atmosphere that tends to reduce the apparent DIC deficit; thus the estimated biological drawdown from observed DIC values in Figure 6 may be underestimated and needs to be corrected for air-sea CO\(_2\) gas exchange from the period of biological drawdown to the sampling time. To account for DIC concentration changes due to gas exchange with the atmosphere, we assumed a constant atmospheric concentration of 390 µatm between 1993 and 2012, and a gas transfer rate (k) of 5 (±1) milli-mol CO\(_2\) m\(^{-2}\) µatm\(^{-1}\) month\(^{-1}\), which is the estimated mean rate for the Southern Ocean area south of 62 °S [Takahashi et al. 2009]. The change in DIC (µmol kg\(^{-1}\) month\(^{-1}\)) due to gas transfer into the mixed layer (ML) of d meters depth is:

\[
\Delta \text{DIC} = k \times \Delta t \times \Delta p\text{CO}_2 / d.
\]
\[ \Delta pCO_2 \text{ (pCO}_{2\text{atm}} - \text{pCO}_{2\text{ML}}) \] was between -143 \( \mu \text{atm} \) and 312 \( \mu \text{atm} \), as pCO\(_2\)\(^{\text{ML}} \) ranged from 533 \( \mu \text{atm} \) to 78 \( \mu \text{atm} \), indicating that there was potential for both oceanic CO\(_2\) uptake and outgassing. Assuming that \( d = 50 \text{ m} \) [Ducklow et al., 2013], we estimate that the monthly \( \Delta \text{DIC} \) due to air-to-sea CO\(_2\) gas exchange was in the range of -14 to 31 \( \mu \text{mol} \) kg\(^{-1}\) month\(^{-1}\). Since the first large phytoplankton blooms generally occur after the sea-ice retreats in November (\( \Delta t \sim 3 \text{ months} \)), we assume that by the time of sampling at the end of January, \( \Delta \text{DIC} \) would fall in the range -43 to 94 \( \mu \text{mol} \) kg\(^{-1}\). The DIC corrected for gas exchange is illustrated as grey dots in Figure 6. While applying the gas exchange correction flattens the regression line (grey line) somewhat, the photosynthesis line (blue) still remains within the estimated error bounds of the gas exchange corrected regression line (grey dotted lines), further emphasizing that photosynthesis is the key biological driver of the summertime carbonate system west of the Antarctic Peninsula.

### 3.3 Nutrient vs. carbon drawdown

Ocean carbon, nitrogen and phosphorus cycles are governed by organic matter production and subsequent remineralization and are strongly correlated on a global average with the proportions C/N/P = 106:16:1 [Redfield, 1958]. Our findings suggest that the carbon-nutrient cycles along the WAP depart from the standard Redfield values (Figure 7). In a few samples, the standing stock of PO\(_4^{3-}\) became depleted before NO\(_3^{-}\), and overall the regression indicates a low N:P ratio of 9.8 \( \pm \) 0.4 in the mixed layer (Figure 7a, black) and N:P = 11.7 \( \pm \) 0.3 for all data (dark grey) relative to the standard Redfield value of 16 molN/mol P. The mole/mole C:P ratio was also considerably smaller than the Redfield ratio (Figure 7b). C:P yielded 43.1 \( \pm \) 2.3 in the mixed layer and 55.0 \( \pm \) 1.7 for all data. However, after applying the gas exchange correction on DIC (see section 3.2), the C:P ratio shifted closer to the Redfield Ratio and resulted in a value of 80.5 \( \pm \) 2.5 (light grey dots and lines). Correcting the DIC for gas exchange shifted the molar ratio from 4.5 \( \pm \) 0.2 (mixed layer depth) and 4.7 \( \pm \) 0.1 (all data) to 6.7 \( \pm \) 0.2 and resulted in a Redfield-like C:N ratio.

### 3.4 Seasonal variability
To get insights into the carbon dynamics during winter, spring, and fall, when direct measurements of DIC, TA and nutrients are either scarce or not available, we developed a regional TA algorithm (based on PAL-LTER summertime data). In combination with seasonal LDEO pCO$_2$, salinity and temperature data, we calculated $\Omega_{\text{arag}}$ for the missing seasons. Due to the weak correlation between PAL-LTER temperature and TA ($r = 0.50$), we based the TA algorithm on salinity only (Figure A2, $r = 0.88$). Applying the Akaike information criterion [Burnham and Anderson, 2002], we determined that TA along the WAP will be best represented by a first order linear model. We then randomly divided the PAL-LTER surface measurements (depth <5 m) into 10 data subsets using the 10-fold cross validation method [Stone, 1974; Breiman, 1996]. Using 9 of the ten data sets we derived a regression model, predicted the TA with the model, and calculated the model coefficients and root mean square errors (RMSE). We repeated these steps so every data subset was left out once. The coefficients for the final model were calculated from the mean of the ten regression coefficients. We found the best fit in the following equation:

$$\text{TA}^{\text{pred}}(\mu\text{mol kg}^{-1}) = 57.01 (\pm 0.88) \times S + 373.86 (\pm 35.26),$$

which resulted in a linear correlation coefficient of $r = 0.88$ and a RMSE of 15.2 µmol kg$^{-1}$ (Figure A2). In combination with the pCO$_2$ measurement precision of 3 µatm, the RMSE of TA prediction resulted in a mean error in calculated $\Omega_{\text{arag}}$ of 0.0219 units and pH$_T$ of 0.0043 [Glover et al., 2011]. Note that the calculated $\Omega_{\text{arag}}$ and pH$_T$ estimates implicitly require that the approximately linear summertime TA-salinity relationship holds for the other seasons, a reasonable assumption if dilution and mixing substantially affect TA patterns.

Summertime LDEO underway pCO$_2$ values were, on average, lower than during the rest of the year (Figure 8a). While only a small percentage of these summertime values reached levels higher than the atmospheric CO$_2$ concentration, 70% of the water samples taken in winter were supersaturated with regard to atmospheric CO$_2$ (>390 µatm). Spring and fall pCO$_2$ values were also generally higher than summertime measurements and ranged from 207 to 506 µatm and 90 to 414 µatm.

Our salinity-based algorithm predicted the majority of all TA ranging between 2200 and 2300 µmol kg$^{-1}$ in all seasons, with the most frequent occurrence of highest TA
in winter and spring (Figure 8b). Some summertime TA was predicted to be as low as 2056 µmol kg\(^{-1}\).

Prediction of seasonal Ω\(_{\text{arag}}\) revealed that surface waters of the WAP were supersaturated with regard to aragonite throughout the years (Figure 8c). The most frequent occurrence of low Ω\(_{\text{arag}}\) was in winter and spring, when most of the predicted values resulted in Ω\(_{\text{arag}}\) < 1.4. 20% of spring and winter values were Ω\(_{\text{arag}}\) < 1.2, with the lowest predicted surface Ω\(_{\text{arag}}\) reaching near aragonite undersaturation in winter. Similar to the LTER observations, predicted summertime Ω\(_{\text{arag}}\) displayed a large range, spanning from 1.1 to 4.1, with the majority of predictions between 1.3 and 1.8. Biological production in summer is sufficiently intense to prevent low Ω\(_{\text{arag}}\) values during the active growing season when its effects might be most pronounced.

### 3.5 Temporal trends

Trend analysis of the PAL-LTER data showed no statistically significant annual trends (at the 95% confidence level) in the measured carbon parameters, temperature or salinity in surface waters in summer between 1993 and 2012 (Table 2). As a comparison, we conducted a trend analysis for the LDEO surface underway pCO\(_2\) data set (1999 – 2013) in the same region. LDEO observations show an increasing, but not statistically significant trend in surface pCO\(_2\), supporting our results above (Table 3). The largest increasing trend was found in fall, (1.9 ± 0.95 µatm yr\(^{-1}\)), but this trend was also slightly outside the confidence interval and therefore statistically not significant.

### 4 Discussion

The 20 year-long PAL-LTER seawater inorganic carbon time-series showed a distinct upper-ocean spatial pattern of onshore–offshore and north – south gradients and suggests that the summertime carbon dynamics are primarily controlled by biological productivity and freshwater input in near-shore areas.

Surface Ω\(_{\text{arag}}\) was distributed across a wide range (<1 to values > 3) in freshwater-influenced areas with salinities S < 32 (Figure 5). To better understand how such a wide range of Ω\(_{\text{arag}}\) at relatively low salinities was possible, we quantified the effect of freshwater and biological production. Mixing of seawater with sea-ice or glacial
meltwater leads to a ‘dilution’ of \( \text{CO}_3^{2-} \) ions and a decrease in \( \Omega_{\text{arag}} \) because \( \text{TA} \) and \( \text{DIC} \) in glacial and sea-ice meltwater are much lower than in seawater [Anderson et al., 2000; Yamamoto-Kawai et al., 2009]. Calculations of salinity normalized \( \Omega_{\text{arag}} \) using sDIC and sTA showed that freshwater input decreased \( \Omega_{\text{arag}} \) by up to 0.2 units along the coast. Despite the negative effect of freshwater on \( \Omega_{\text{arag}} \), the water in the south was nonetheless highly supersaturated with \( \text{CaCO}_3 \). The salinity normalized DIC in the near-shore southern region of the PAL-LTER sampling grid was up to 177 \( \mu \text{mol kg}^{-1} \) lower than elsewhere, suggesting that near-shore phytoplankton blooms balanced out the negative effect of freshwater on \( \Omega_{\text{arag}} \) and even increased \( \Omega_{\text{arag}} \) by up to 2 units. In 2005, when the above-described pattern was particularly conspicuous, high Chl a (up to 20 \( \mu \text{g/L} \)) in the southern coastal area of the sampling grid provides further evidence that high primary productivity led to the observed high \( \Omega_{\text{arag}} \) despite the presence of freshwater. Similar results were found after the calving event of the Mertz glacier tongue in eastern Antarctica, where enhanced primary productivity increased the \( \Omega_{\text{arag}} \) and thereby counteracted the effect of dilution by meltwater input [Shadwick et al., 2013].

Our findings of onshore-offshore and latitudinal gradients of carbon parameters are supported by previous results that suggest similar patterns for several physical and biogeochemical parameters. Summertime surface temperature, salinity and \( \text{NO}_3^- + \text{NO}_2^- \) are generally lower close to the coast, while Chl a, primary production, \( \text{Si(OH)}_2 \) and water column stability decrease from the coast toward the open ocean [Smith, 2001; Garibotti et al., 2003; Vernet et al., 2008]. The freshwater along the coast may originate, to a large part, from melting of glacial ice and snow [Meredith et al., 2013]. Such glacial and snow-melt plumes have been correlated with increased primary production due to a stabilization of the mixed layer, which creates favorable conditions for phytoplankton blooms [Dierssen et al., 2002]. This in turn is thought to be the dominant control of the onshore-offshore gradient of phytoplankton variability and associated biologically-impacted parameters. The north-south gradients possibly reflect the timing of phytoplankton blooms in the north and south. As such, blooms in the north occur sooner than blooms in the south [Smith et al., 2008] – thus on average the PAL-LTER January cruise takes place after the bloom in the north, and during the blooms in the south. This may also be the reason for the nutrient depletion along the coast, despite low biological
productivity at the time of sampling in the north (Figure 4h and i). However, it is important to note that as a result of changes in ice cover, cloud formation and wind over the past 30 years, biological productivity has increased in the southern part of the WAP and significantly decreased north of 63°S [Montes-Hugo et al., 2009]. The observed DIC drawdown in the winter water (Figure 5 and A3) may be a result of biological productivity, which is supported by previous observations of Chl a maxima in the euphotic part of the winter water, likely due to increased iron concentrations there [Garibotti et al., 2003; Garibotti, 2005]. However, it is also likely that lateral advection or vertical mixing of low DIC water into the winter water have caused this signal.

Low $\Omega_{arag}$ values (< 1.35) observed offshore coincided with surface waters supersaturated with regard to atmospheric CO$_2$, salinities >33.5, and temperatures between 1.3 – 1.5 °C (not shown). These physical properties are associated with modified UCDW, a mixture between UCDW and Antarctic Surface Water [Smith et al., 1999] and indicate that upwelling of DIC and TA rich water into the mixed layer may lead to lower $\Omega_{arag}$ conditions offshore [Carrillo et al., 2004].

The PAL-LTER data indicate N:P uptake ratios lower than the Redfield ratio of 16:1, and uptake ratios similar to our findings (14:1) are common for the polar region of the Southern Ocean [Weber and Deutsch, 2010; Martiny et al., 2013]. Our observed low ratio may be the result of a high abundance of diatoms with low N/P ratios in this cold and nutrient-rich environment [Arrigo, 1999; Arrigo et al., 2002; Green and Sambrotto, 2006; Martiny et al., 2013]. Rubin et al., [1998] observed a similar N/P ratio of 13.0 ± 1.2 in the mixed layer south of the Polar Front, and an even lower N/P ratio of 11.3 ± 0.3 was observed in the iron-spiked mixed layer during the iron fertilization experiment in the Subantarctic South Pacific [Hales and Takahashi, 2012]. Consistent with the low N/P ratio, the observed C:P ratio (80.5 ± 2.5, corrected for gas exchange) was also lower than the classic Redfield ratio. This indicates that the regional phosphate cycle shows non-Redfield behavior, which is in agreement with the observed C:P ratio of 91.4 ± 7.9 in the mixed layer south of the Polar Front [Rubin et al., 1998]. For the same region, Rubin et al., [1998] describe Redfield behavior of C/N nutrient utilization, which corresponds with our gas exchange corrected C/N nutrient utilization ratio of 6.7 ± 0.2. Recently published work suggests that C/N/P ratios exhibit a latitudinal pattern, with a range of 66:11:1 to
74:13:1 at higher latitudes in the Southern Ocean [Martiny et al., 2013] and can therefore be significantly lower than what we found in this study.

TA variability was largely driven by dilution through freshwater input and mixing (Figure 5), which is well characterized by the salinity-derived TA relationship presented in section 3.4. However, biological mechanisms such as photosynthesis, respiration, CaCO_3 precipitation and dissolution also played an important role in controlling TA concentrations in the water column and at the surface (Figure 6). Neglecting these important drivers may be responsible for the large RMSE of our predicted TA (Figure A2) relative to other studies that either had additional parameters at hand (i.e. O_2 or nutrients) to derive inorganic carbon system parameters in coastal environments [Juranek et al., 2009; Kim et al., 2010; Evans et al., 2013] or that used salinity algorithms to predict TA in open-ocean regions [Takahashi et al., 2014]. Furthermore, TA varied by more than 70 µmol kg^{-1} at salinities >33.7, which led to an unbalanced distribution of residuals (Figure A2c). Increasing TA at higher salinities and nearly constant DIC concentrations has been observed before in Arctic and Antarctic regions [Dieckmann et al., 2008; Fransson et al., 2011; Rysgaard et al., 2012; Shadwick et al., 2014; Legge et al., 2015] and may be due to formation of ikaite crystals (CaCO_3.6H_2O) [Suess et al., 1982] that store TA in sea-ice and, upon melting, release the excess TA into the surface water [Rysgaard et al., 2012, 2013]. However, reasons for the observed increasing TA at higher salinities along the WAP remain speculative, since direct evidence of ikaite formation/dissolution such as an increase in DIC associated with TA increase is missing (Figure 6). A combination of other mechanisms, such as upwelling of high salinity – high TA waters concomitant with biological DIC drawdown, could have increased TA:DIC ratios at high salinities. Finally, the WAP region is very dynamic, with large seasonal changes that may affect the carbon system in ways not representable by one algorithm and may therefore require seasonally adjusted algorithms.

Despite of the above-described shortcomings in our salinity-derived TA algorithm, the estimated Ω_{arag} values give a useful overview of the seasonal distribution and variability of Ω_{arag} (Figure 8). Error propagation of pCO_2 measurement precision and TA prediction accuracy suggests that the predicted error for Ω_{arag} may be as little as 0.02 [Glover et al., 2011]. The seasonal estimations of Ω_{arag} suggest that some winter and
springtime $\Omega_{\text{arag}}$ were near $\Omega_{\text{arag}} = 1$ and 20% were between 1.0 and 1.2 (Figure 8).

Short-term exposure to low levels of $\Omega_{\text{arag}}$ may cause severe dissolution of live pteropod shells and has already been observed in the Scotia Sea [Bednaršek et al., 2012]. Surface aragonite undersaturation along the WAP may be a result of ocean acidification and may not have been common during preindustrial times [Hauri et al., under review].

The large uncertainties in our estimated temporal trends are caused inherently by the large spatial and temporal variability of our data. Nevertheless, our mean rates of 1.45 ± 2.97 for summer and 0.43 ± 0.77 $\mu$atm yr$^{-1}$ for winter suggest that the surface water pCO$_2$ has been increasing at a slower rate than the atmospheric pCO$_2$ rate of about 1.9 $\mu$atm yr$^{-1}$, and that the air-to-sea CO$_2$ driving potential has been increasing. Our results may be compared with the recent analysis of the 2002-2015 time-series data obtained across the Drake Passage by Munro et al. [in press]. In the waters south of the Polar Front (their Zone 4, closest to the LTER area), they observed that the surface water pCO$_2$ increased at a rate of 1.30 ± 0.85 $\mu$atm yr$^{-1}$ in summer and 0.67 ± 0.39 $\mu$atm yr$^{-1}$ in winter, which are comparable with ours along the WAP. We observed the strongest but still statistically insignificant increase in surface pCO$_2$ in fall (1.9 $\mu$atm year$^{-1}$, $p = 0.0685$).

This increase corresponds with the mean atmospheric pCO$_2$ increase of 1.9 $\mu$atm per year, which causes a pHT decrease of about 0.02 per decade [Takahashi et al., 2014]. Interestingly, Stammerjohn et al., [2008a, 2008b] found that sea ice extent and wind are also changing most rapidly in spring and fall, which may enhance sea-air gas exchange and therefore facilitate positive pCO$_2$ trends. Furthermore, it is likely that the strong counter effect of biological productivity successfully masks the pCO$_2$ trend in summer, and decreased gas exchange due to sea ice weakens the trend in winter. However, the WAP climate and oceanography are regulated by large-scale atmospheric patterns, such as El Niño Southern Oscillation and Southern Annular Model [Stammerjohn et al., 2008a], which may also influence the region’s inorganic carbon chemistry on an interannual scale. A longer measurement period may be needed in order to be able to distinguish with certainty between natural variability and secular trends [Henson et al., 2010].

5 Conclusions
This study gives new insights into the spatial and temporal variability of the WAP inorganic carbon system and its main physical and biological drivers. In particular, we found that large inorganic carbon drawdown through biological production in summer caused high near-shore Ω_{arag}, despite glacial and sea-ice melt water input. Furthermore, the data do not show a significant long-term trend in any of the inorganic carbon chemistry variables measured. Continuation and expansion of the inorganic carbon chemistry timeseries across other seasons is necessary to distinguish between natural variability and secular trends and to better understand synergistic effects of ocean acidification and climate change. Due to the region’s physical complexity of circulation and forcing, and strong dynamic response to climate variability, we recommend development of a highly resolved biogeochemical model to complement our observational work. Implementation of modeling studies will improve our mechanistic understanding of how interannual variability and anthropogenic climate change impact the inorganic carbon chemistry along the WAP, which is imperative to predict the potential impact on the unique WAP ecosystem.

Figures.

**Figure 1.** Map of the Western Antarctic Peninsula (WAP) and study area of the Palmer Antarctica Long Term Ecological Research (PAL-LTER) project. The red box shows the main study grid that has been sampled for inorganic carbon chemistry since 1993, and is defined in this study as the central sub-region. The black squares indicate the stations (20 km apart) arranged in onshore to offshore lines spaced 100 km apart along the peninsula. The inorganic carbon measurements from stations south of the central sub-region were only added in 2009. The central sub-region also contains surface underway pCO$_2$ observations that were used in the trend analysis (Section 3.5). P: Palmer Station on Anvers Island; A: Adelaide Island; and MB: Marguerite Bay.

**Figure 2.** Comparison of deep-water (off shelf) dissolved inorganic carbon (DIC, µmol kg$^{-1}$) and total alkalinity (TA, µmol kg$^{-1}$) data from Palmer Station Long Term Ecological Research (PAL-LTER) with other available cruise data. a) Station locations, b) DIC and c) TA depth profiles from PAL-LTER cruises (1998-2012), World Ocean Circulation Experiment (WOCE) and Ocean – Variability, Predictability, and Change (CLIVAR) cruises along parts of sections A21 (2006, 2009) and S4P (1992, 2011). The directly measured parameters are listed in the parentheses and were used to calculate TA if not directly measured.

**Figure 3.** Depth profiles of aragonite saturation state ($\Omega_{\text{arag}}$) for the years 1993 through 2012. The aragonite saturation horizon for each year is located where the profile crosses the black line ($\Omega_{\text{arag}} = 1.0$).

**Figure 4.** Maps of summertime averages of surface a) pCO$_2$, b) pH, c) aragonite saturation state ($\Omega_{\text{arag}}$), d) total alkalinity (TA, µmol kg$^{-1}$), e) salinity, f) dissolved inorganic carbon (DIC, µmol kg$^{-1}$), and g) salinity-normalized DIC (sDIC, µmol kg$^{-1}$) across years with available DIC and TA measurements (1993-1999, 2001-2002, and 2005-2012). Salinity-normalized PO$_4^{3-}$ (s PO$_4^{3-}$, µmol kg$^{-1}$) and salinity normalized NO$_3^-$ (s NO$_3^-$, µmol kg$^{-1}$) were averaged across 1993-1996, 1999, and 2001-2012. Averages
are only shown for regions where samples were taken in five or more years. Occupied stations are shown by black dots.

**Figure 5.** Scatter plots of dissolved inorganic carbon (DIC, $\mu$mol kg$^{-1}$) illustrated as diamonds and total alkalinity (TA, $\mu$mol kg$^{-1}$) illustrated as dots as a function of salinity. The data points are color coded by the aragonite saturation state ($\Omega_{\text{arag}}$). The solid lines illustrate the dilution lines using $S = 34.7$, $TA = 2350 \mu$mol kg$^{-1}$, and DIC = 2253 $\mu$mol kg$^{-1}$ as end members for UCDW, and $S = 0$, $TA = 300 \mu$mol kg$^{-1}$, and DIC = 300 $\mu$mol kg$^{-1}$ as end members for melt water [Yamamoto-Kawai et al., 2009]. WW = Winter water ($T <= -1.2 \, ^{\circ}\mathrm{C}; \, 33.85 <= S <= 34.13$), UCDW = Upper Circumpolar Deep Water ($1.7 \, ^{\circ}\mathrm{C} => T <= 2.13 \, ^{\circ}\mathrm{C}; \, 34.54 <= S <= 34.75$) following [Martinson et al., 2008].

**Figure 6.** Salinity-normalized total alkalinity (sTA, $\mu$mol kg$^{-1}$) as a function of salinity-normalized dissolved inorganic carbon (sDIC, $\mu$mol kg$^{-1}$) for waters shallower than the Upper Circumpolar Deep Water (UCDW, black circles). A linear fit between sTA and sDIC is shown by the black solid line. The dotted black lines indicate $2\sigma$ for estimated measurement precision of $\sigma = +/\ - 5 \mu$mol kg$^{-1}$. The blue line illustrates the trend if sTA and sDIC of the winter water (WW) were only influenced by photosynthesis (1:-6.2). Grey dots represent sTA as a function of sDIC corrected for gas exchange in the waters above the WW, and the linear fits with the estimated measurement precision are the grey solid and dashed lines respectively. WW: $T <= -1.2 \, ^{\circ}\mathrm{C}; \, 33.85 <= S <= 34.13$, UCSW: $1.7 \, ^{\circ}\mathrm{C} => T <= 2.13 \, ^{\circ}\mathrm{C}; \, 34.54 <= S <= 34.75$, following [Martinson et al., 2008].

**Figure 7.** Plot of salinity-normalized nutrients and dissolved inorganic carbon (sDIC, $\mu$mol kg$^{-1}$), a) sPO$_4^{3-}$ ($\mu$mol kg$^{-1}$) versus sNO$_3^-$ ($\mu$mol kg$^{-1}$), b) sPO$_4^{3-}$ versus sDIC, and c) sNO$_3^-$ versus sDIC. Observations within the mixed layer (~ depth < 50 m) are illustrated by black circles. The light grey dots in b) and c) show sDIC corrected for gas exchange as a function of sPO$_4^{3-}$ and sNO$_3^-$, respectively. A linear fit is represented by the solid black line for the mixed layer, by the solid grey line for all data, and by the light grey line for the gas-exchange corrected sDIC in b) and c). The dashed black lines are the nutrient
drawdown lines using the corresponding Redfield ratio and data from the Upper Circumpolar Deep Water (UCDW) as end-members.

**Figure 8.** Seasonal variability of inorganic carbon system. Relative frequency distribution of a) measured underway surface partial pressure $pCO_2$ ($\mu$atm), b) predicted surface total alkalinity (TA, $\mu$mol kg$^{-1}$) from underway salinity, and c) predicted surface aragonite saturation state ($\Omega_{arag}$) in summer (red), fall (orange), winter (blue), and spring (yellow). The x-axis represents the range of $\Omega_{arag}$, TA, and $pCO_2$ with a relative frequency distribution $>= 0.0001$. 
Table 1. Comparison of Lamont-Doherty Earth Observatory of Columbia University (LDEO) underway pCO$_2$ (µatm) data [Takahashi et al., 2015] with the pCO$_2$ (µatm) derived from PAL-LTER discrete surface samples over the Palmer-Long Term Ecological Research (PAL-LTER) sampling grid. The PAL-LTER discrete pCO$_2$ sample values were computed using the dissolved inorganic carbon (DIC, µmol kg$^{-1}$) and total alkalinity (TA, µmol kg$^{-1}$). The analysis is based on the data after removing outliers as explained in the text.

| Year | LDEO (µatm) | PAL-LTER (µatm) | Mean (std) | $r$ | Slope (±0.06) | Intercept (±17.0) | n |
|------|-------------|-----------------|------------|----|---------------|-------------------|---|
| 2005 | 293 (79)    | 322 (75)        | 0.94       | 1.05 | -45.7 (±17.0) | 49                |
| 2006 | 248 (46)    | 248 (48)        | 0.90       | 0.95 | 13.2 (±15)    | 55                |
| 2007 | 261 (61)    | 237 (59)        | 0.87       | 1.04 | 14.7 (±18.5)  | 60                |
| 2008 | 340 (28)    | 299 (37)        | 0.53       | 0.61 | 158 (±42.5)   | 48                |
| 2009 | 318 (24)    | 292 (37)        | 0.58       | 0.47 | 179 (±37.9)   | 27                |
| 2010 | 327 (35)    | 305 (27)        | 0.54       | 1.62 | -167 (±174)   | 20                |
| 2011 | 226 (98)    | 233 (101)       | 0.93       | 0.97 | 0.60 (±21.4)  | 21                |
| 2012 | 354 (36)    | 279 (30)        | 0.46       | 1.44 | -47.7 (±172)  | 21                |
| All  | 290 (69)    | 275 (65)        | 0.82       | 1.08 | -5.57 (±12.2) | 300               |
Table 2. Mean annual trend (1993-2012) of Palmer-Long Term Ecological Research (PAL-LTER) surface (depth < 5 m) carbonate chemistry and hydrography from the Western Antarctic Peninsula (central sub-region). Regression statistics include the mean annual rate (yr\(^{-1}\)), standard error (SE), number of measurements (NM), number of years (NY), r-square, and p-value for aragonite saturation state (\(\Omega_{\text{arag}}\)), pH, dissolved inorganic carbon (DIC, \(\mu\text{mol kg}\(^{-1}\)), total alkalinity (TA, \(\mu\text{mol kg}\(^{-1}\)), temperature (°C), and salinity. Trends with a p-value < 0.05 are statistically significant at the 95% confidence level (values bolded). Points that were outliers at 95% probability level were excluded (o).

| Parameter          | Rate (yr\(^{-1}\)) ± SE | NM(o) | NY | \(r^2\) | p-value |
|--------------------|--------------------------|-------|----|---------|---------|
| \(\Omega_{\text{arag}}\) | 0.001 ± 0.01             | 892(17)| 18 | 0.04    | 0.9127  |
| pH                 | 0.002 ± 0.002            | 892(8)| 18 | 0.03    | 0.2784  |
| DIC (\(\mu\text{mol kg}\(^{-1}\)) | -0.18 ± 1.03            | 907(0)| 18 | 0.00    | 0.8677  |
| TA (\(\mu\text{mol kg}\(^{-1}\)) | 0.58 ± 0.63              | 907(0)| 18 | 0.05    | 0.3681  |
| Temperature (°C)   | -0.01 ± 0.02             | 1076(8)| 20 | 0.01    | 0.4629  |
| Salinity           | 0.01 ± 0.01              | 1060(8)| 20 | 0.12    | 0.1349  |
**Table 3.** Trend analysis (1999-2013) of Lamont-Doherty Earth Observatory of Columbia University (LDEO) surface continuous underway pCO$_2$ (µatm), salinity and temperature (°C) measurements from within the central sub-region of the Palmer-Long Term Ecological Research (PAL-LTER) sampling grid (Figure 1, red box). Regression statistics include mean rate, standard error (SE), number of measurements (NM), number of years (NY), r-square, and p-value. Trends with a p-value < 0.05 would be considered statistically significant at the 95% confidence level.

| Parameter | Season | Rate ± SE | NM   | NY | r$^2$ | p-value |

A scatter plot showing the relationship between sTA (μmol kg$^{-1}$) and sDIC (μmol kg$^{-1}$). The plot includes data points representing different processes such as photosynthesis, dissolution, precipitation, and respiration. The graph has axes labeled sTA (μmol kg$^{-1}$) on the y-axis and sDIC (μmol kg$^{-1}$) on the x-axis. Notably, there are markers indicating WW and UCDW.

Appendix

Figure A1.
Comparison of Lamont-Doherty Earth Observatory of Columbia University (LDEO) continuous underway pCO₂ (µatm) over the Palmer-Long Term Ecological Research (PAL-LTER) sampling grid (Takahashi et al., 2015) with pCO₂ (µatm) derived from PAL-LTER dissolved inorganic carbon (DIC, µmol kg⁻¹) and total alkalinity (TA, µmol kg⁻¹) from discrete samples taken during the same cruise (2005-2012). PAL-LTER pCO₂ outliers that underestimate/overestimate pCO₂ relative to the underway observations by more than 150 µatm were removed. The two data sets were spatially matched, with a 1 km distance threshold. See Table 1 for statistics.

Figure A2.
Evaluation of total alkalinity (TA) algorithm. a) Measured TA as a function of salinity and temperature (color), b) measured TA vs. predicted TA, and c) residuals vs. salinity.

Figure A3
Scatterplots of depth and inorganic carbon chemistry superimposed on potential temperature-salinity diagrams. Shown in color are a) depth, b) dissolved inorganic carbon (DIC, µmol kg⁻¹), c) total alkalinity (TA, µmol kg⁻¹), and d) aragonite saturation state (Ω_arag). The bold black line illustrates the freezing point as a function of temperature and salinity. Grey lines mark densities. Water masses are indicated and labeled in a): WW = Winter Water, AASW = Antarctic Surface Water in summer, ACC-core UCDW = Antarctic Circumpolar Current-core Upper Circumpolar Deep Water, DW = local Deep Water end member, following Martinson et al., [2008].
