Abstract

**Background:** The study of exotic nuclei far from the $\beta$ stability line is stimulated by the development of radioactive ion beam facilities worldwide and brings opportunities and challenges to existing nuclear theories. Including self-consistently the nuclear superfluidity, deformation, and continuum effects, the deformed relativistic Hartree-Bogoliubov theory in continuum (DRHBc) has turned out to be successful in describing both stable and exotic nuclei. Due to several challenges, however, the DRHBc theory has only been applied to study light nuclei so far.

**Purpose:** The aim of this work is to develop the DRHBc theory based on the point-coupling density functionals and extend it to provide a unified description for all even-even nuclei in the nuclear chart by overcoming all possible challenges.

**Method:** The nuclear superfluidity is taken into account via Bogoliubov transformation. Densities and potentials are expanded in terms of Legendre polynomials to include the axial deformation degrees of freedom. Sophisticated relativistic Hartree-Bogoliubov equations in coordinate space are solved in the Dirac Woods-Saxon basis to consider the continuum effects.

**Results:** Numerical checks for energy cutoff, angular momentum cutoff, Legendre expansion, pairing strength, and (un)constrained calculations are performed from light nuclei to heavy nuclei. Combined with the successful density functional PC-PK1, ground-state properties of even-even Nd isotopes are obtained using the developed theory and compared with the spherical nuclear mass table based on the relativistic continuum Hartree-Bogoliubov (RCHB) theory as well as the data available. The calculated binding energies are in very good agreement with the existing experimental values with a rms deviation of 0.958 MeV, which is remarkably smaller than 8.301 MeV in the spherical case. Meanwhile, a better reproduction of two-neutron separation energies is obtained. The experimental quadrupole deformations and charge radii are also reproduced well. The predicted proton and neutron drip-line nuclei for Nd isotopes are respectively $^{120}$Nd and $^{214}$Nd, in contrast with $^{126}$Nd and $^{228}$Nd in the RCHB theory. The thickness of the neutron skin and the particles number in continuum for Nd isotopes on the neutron-rich side are investigated. An interesting decoupling between the oblate shape $\beta_2 = -0.273$ contributed by bound states and the nearly spherical one
$\beta_2 = 0.047$ contributed by continuum is found in $^{214}$Nd. Contributions of different single-particle states to the total neutron density in $^{214}$Nd are investigated and an exotic neutron skin phenomenon is suggested for $^{214}$Nd. The proton radioactivity beyond the proton drip line is discussed and $^{114}$Nd, $^{116}$Nd, and $^{118}$Nd are predicted to be candidates for two-proton or even multi-proton radioactivity.

**Conclusions:** The DRHBc theory based on the point-coupling density functionals is developed and detailed numerical checks are performed. The techniques to construct the DRHBc mass table for even-even nuclei are explored. The DRHBc theory is extended to study heavier nuclei beyond magnesium isotopes. Taking Nd isotopes as examples, the experimental binding energies, two-neutron separation energies, quadrupole deformations, and charge radii are reproduced rather well. The deformation and continuum play essential roles in the description of nuclear masses and prediction of drip-line nuclei. By examining the single-particle levels in the canonical basis and their contributions to the total density, the thickness of the neutron skin, the particles number in continuum, and the Coulomb barrier, the exotic structures including the neutron skin and the proton radioactivity are predicted.

I. INTRODUCTION

In nuclear physics, the study of the properties of exotic nuclei with extreme numbers of protons or neutrons is one of the top priorities, as it can lead to new insights into the origins of the chemical elements in stars and star explosions [1]. Although radioactive ion beams (RIB) have extended our knowledge of nuclear physics from stable nuclei to exotic ones far away from the valley of stability, it is still a dream to reach the neutron drip line up to mass number \( A \sim 100 \) with the new generation of RIB facilities developed around the world, including the Cooler Storage Ring (CSR) at the Heavy Ion Research Facility in Lanzhou (HIRFL) in China [2], the RIKEN Radioactive Ion Beam Factory (RIBF) in Japan [3], the Rare Isotope Science Project (RISP) in Korea [4], the Facility for Antiproton and Ion Research (FAIR) in Germany [5], the Second Generation System On-Line Production of Radioactive Ions (SPIRAL2) at GANIL in France [6], the Facility for Rare Isotope Beams (FRIB) in the USA [7], etc.

The nuclear mass or binding energy is of crucial importance not only in nuclear physics, but also in other fields, such as astrophysics [8, 9]. It has been always a priority in nuclear physics to explore the limit of nuclear binding [10–12]. Experimentally, the existence of about 3200 isotopes has been confirmed [13] and the masses of about 2500 nuclides have been measured [14, 15]. The proton drip line has been determined up to neptunium [16], but the neutron drip line is known only up to neon [13]. In the foreseeable future, most of neutron-rich nuclei far from the valley of stability seem still beyond the experimental capability. Therefore, it is urgent to develop a theoretical nuclear mass table with predictive power to grasp a complete understanding of the nature.

Theoretically, a lot of efforts have been made to predict nuclear masses and to explore the great unknowns of the nuclear landscape [10, 12, 17–26]. Precise descriptions of nuclear masses have been achieved with various macroscopic-microscopic models [17–20]. Several Skyrme or Gogny Hartree-Fock-Bogoliubov mass models have been developed based on the non-relativistic density functional theory [21]. On the relativistic side, many investigations have been done and significant progresses have been made based on the covariant density functional theory [12, 22–26].

The covariant density functional theory (CDFT) has been proved to be a powerful theory in nuclear physics by its successful description of many nuclear phenomena [1, 27–34]. As a
microscopic and covariant theory, the CDFT has attracted a lot of attention in recent years for many attractive advantages, such as the automatic inclusion of nucleonic spin degree of freedom, explaining naturally the pseudospin symmetry in the nucleon spectrum \(^{35-40}\) and the spin symmetry in anti-nucleon spectrum \(^{40-42}\), and the natural inclusion of the nuclear magnetism \(^{43}\), which plays an important role in nuclear magnetic moments \(^{44-48}\) and nuclear rotations \(^{31, 49-59}\).

Based on the CDFT, taking into account both bound states and continuum via the Bogoliubov transformation in a microscopic and self-consistent way, the relativistic continuum Hartree-Bogoliubov (RCHB) theory was developed in Refs. \(^{60, 61}\). With the pairing correlation and the coupling to the continuum considered, the RCHB theory has achieved great success in reproducing and interpreting the halo in \(^{11}\)Li \(^{60}\), predicting the giant halo phenomena \(^{62-64}\), reproducing the interaction cross section and charge-changing cross sections in sodium isotopes \(^{65}\) and other light exotic nuclei \(^{66}\), interpreting the pseudospin symmetry in exotic nuclei \(^{36, 37}\), and making predictions of new magic numbers in superheavy nuclei \(^{67}\) and neutron halos in hypernuclei \(^{68}\). Recently, based on the RCHB theory with point-coupling density functional PC-PK1 \(^{69}\), the first nuclear mass table including continuum effects has been constructed and the continuum effects on the limits of the nuclear landscape have been studied \(^{12}\). It is demonstrated that the continuum effects are crucial for drip-line locations and there are totally 9035 nuclei with \(8 \leq Z \leq 120\) predicted to be bound, which remarkably extends the existing nuclear landscapes. The RCHB mass table has been applied to investigate \(\alpha\)-decay energies \(^{70}\) and proton radioactivity \(^{71}\).

Except for doubly-magic nuclei, most nuclei in the nuclear chart deviate from the spherical shape. To provide a proper description of deformed exotic nuclei, the deformed relativistic Hartree-Bogoliubov theory in continuum (DRHBc) with the meson-exchange density functional was developed in Refs. \(^{72, 73}\). Inheriting the advantages of RCHB theory and including the deformation degree of freedom, the DRHBc theory was applied to study magnesium isotopes and an interesting shape decoupling between the core and the halo was predicted in \(^{44}\)Mg and \(^{42}\)Mg \(^{72, 73}\). The DRHBc theory has been extended to the version with density-dependent meson-nucleon couplings \(^{74}\), and to incorporate the blocking effect \(^{75}\). The success of DRHBc theory has been demonstrated in resolving the puzzles concerning the radius and configuration of valence neutrons in \(^{22}\)C \(^{76}\), and studying particles in the classically forbidden regions for magnesium isotopes \(^{77}\).
The deformation plays an important role in the description of nuclear masses and affects the location of neutron drip line [12]. It is therefore necessary to construct an upgraded mass table including simultaneously the deformation and continuum effects using the DRHBc theory.

It is quite challenging to include both the deformation and continuum effects in coordinate space. In the DRHBc theory, the coupled relativistic Hartree-Bogoliubov equations are solved by the expansion on the Dirac Woods-Saxon basis [78]. It is numerically much more complicated than the RCHB theory. So far, the DRHBc theory has been applied to light nuclei only [72–77]. There are a lot of difficulties to be overcome in order to provide a unified description for all nuclei in the nuclear chart with the DRHBc theory. In particular, it is not easy to block the correct orbit(s) for the odd nucleon(s) to determine the ground state of an odd-$A$ or odd-odd nucleus [12, 75, 79]. Last but not the least, so far the DRHBc theory is based on the meson-exchange density functionals. It is necessary to develop the DRHBc theory with point-coupling density functionals to adopt the successful PC-PK1.

In this work, the DRHBc theory based on the point-coupling density functionals is developed and its application for even-even nuclei is discussed in detail. The formulism is presented in Sec. II. Numerical checks are performed from light nuclei to heavy nuclei, and the details to construct a DRHBc mass table for even-even nuclei are suggested in Sec. III. As examples, the DRHBc calculated results for neodymium isotopes are compared with the RCHB mass table [12] and the data available [15, 80, 81] in Sec. IV. A summary is given in Sec. V.

II. THEORETICAL FRAMEWORK

The DRHBc theory based on the meson-exchange density functionals has been developed [72] and the details can be found in Ref. [73]. In this paper the DRHBc theory with point-coupling density functionals is developed and its formulism is presented in the following in brief.
The point-coupling density functional starts from the following Lagrangian density [1]:

\[
\mathcal{L} = \bar{\psi}(i\gamma_\mu \partial^\mu - M)\psi - \frac{1}{2} \alpha_S(\bar{\psi}\gamma_\mu\psi)(\bar{\psi}\gamma_\mu\psi) \\
- \frac{1}{2} \alpha_V(\bar{\psi}\gamma_\mu\psi)(\bar{\psi}\gamma_\mu\psi) - \frac{1}{2} \alpha_{TV}(\bar{\psi}\gamma_\mu\psi)(\bar{\psi}\gamma_\mu\psi) \\
- \frac{1}{2} \alpha_{TS}(\bar{\psi}\gamma_\mu\psi)(\bar{\psi}\gamma_\mu\psi) - \frac{1}{3} \beta_S(\bar{\psi}\psi)^3 \\
- \frac{1}{4} \gamma_S(\bar{\psi}\psi)^4 - \frac{1}{4} \gamma_V[(\bar{\psi}\gamma_\mu\psi)(\bar{\psi}\gamma_\mu\psi)]^2 \\
- \frac{1}{2} \delta_S \partial_\nu(\bar{\psi}\psi)\partial^\nu(\bar{\psi}\psi) - \frac{1}{2} \delta_V \partial_\nu(\bar{\psi}\gamma_\mu\psi)\partial^\nu(\bar{\psi}\gamma_\mu\psi) \\
- \frac{1}{2} \delta_{TV} \partial_\nu(\bar{\psi}\gamma_\mu\psi)\partial^\nu(\bar{\psi}\gamma_\mu\psi) \\
- \frac{1}{2} \delta_{TS} \partial_\nu(\bar{\psi}\gamma_\mu\psi)\partial^\nu(\bar{\psi}\gamma_\mu\psi) \\
- \frac{1}{4} F_{\mu\nu} F^{\mu\nu} - e\bar{\psi}\gamma_\mu \frac{1}{2} A_\mu \psi,
\]

where \(M\) is the nucleon mass, \(e\) is the charge unit, and \(A_\mu\) and \(F_{\mu\nu}\) are the four-vector potential and field strength tensor of the electromagnetic field, respectively. Here \(\alpha_S, \alpha_V, \alpha_{TS}\), and \(\alpha_{TV}\) represent the coupling constants for four-fermion terms, \(\beta_S, \gamma_S\), and \(\gamma_V\) are those for the higher-order terms which are responsible for the medium effects, and \(\delta_S, \delta_V, \delta_{TS}\), and \(\delta_{TV}\) refer to those for the gradient terms which are included to simulate the finite-range effects. The subscripts \(S, V,\) and \(T\) stand for scalar, vector, and isovector, respectively. The isovector-scalar channel including the terms \(\alpha_{TS}\) and \(\delta_{TS}\) in Eq. (1) are neglected since including the isovector-scalar interaction does not improve the description of nuclear ground-state properties [82].

From the Lagrangian density of Eq. (1), the energy density functional for the nuclear system can be constructed under the mean-field and no-sea approximations. By minimizing the energy density functional with respect to the densities, one obtains the Dirac equation for nucleons within the relativistic mean-field framework [1]. The pairing correlation is crucial in the description of open-shell nuclei. The conventional BCS theory used extensively in describing the pairing correlation turns out to be an insufficient approach for exotic nuclei [83]. The relativistic Hartree-Bogoliubov (RHB) theory can provide a unified and self-consistent treatment of both the mean field and the pairing correlation [61, 84–86], and can describe the exotic nuclei properly in the coordinate space [61] or the Dirac Woods-Saxon basis [72].
The RHB equation reads

$$
\left( \hat{h}_D - \lambda_\tau \hat{\Delta} - \hat{\Delta}^* - \hat{h}_D^* + \lambda_\tau \right) \begin{pmatrix} U_k \\ V_k \end{pmatrix} = E_k \begin{pmatrix} U_k \\ V_k \end{pmatrix},
$$

(2)

where $\hat{h}_D$ is the Dirac Hamiltonian, $\hat{\Delta}$ is the pairing field, $\lambda_\tau$ is the Fermi energy for neutron or proton ($\tau = n, p$), $E_k$ is the quasiparticle energy, and $U_k$ and $V_k$ are the quasiparticle wave functions.

The Dirac Hamiltonian in the coordinate space is

$$h_D(r) = \alpha \cdot p + V(r) + \beta[M + S(r)],$$

(3)

with the scalar and vector potentials

$$S(r) = \alpha_s \rho_S + \beta_s \rho_S^2 + \gamma_S \rho_S^3 + \delta_S \Delta \rho_S,$$

(4)

$$V(r) = \alpha_V \rho_V + \gamma_V \rho_V^3 + \delta_V \Delta \rho_V + eA^0 + \alpha_{TV} \tau_3 \rho_3 + \delta_{TV} \tau_3 \Delta \rho_3,$$

(5)

constructed by various densities

$$\rho_S(r) = \sum_{k>0} V_k^\dagger(r) \gamma_0 V_k(r),$$

$$\rho_V(r) = \sum_{k>0} V_k^\dagger(r) V_k(r),$$

(6)

$$\rho_3(r) = \sum_{k>0} V_k^\dagger(r) \tau_3 V_k(r).$$

According to the no-sea approximation, the summations in above equations are performed over the quasiparticle states with positive energies in the Fermi sea.

The pairing potential is

$$\Delta(r_1 s_1 p_1, r_2 s_2 p_2) = \sum_{s'_1 p'_1} V_{pp}^{(r_1, r_2; s_1 p_1, s_2 p_2, s'_1 p'_1, s'_2 p'_2)} \times \kappa(r_1 s'_1 p'_1, r_2 s'_2 p'_2),$$

(7)

where $s$ represents the spin degree of freedom, $p$ represents the upper or lower component of the Dirac spinors, $\kappa(r_1 s'_1 p'_1, r_2 s'_2 p'_2)$ is the pairing tensor [79], and $V_{pp}$ is the pairing interaction in the particle-particle channel. Here a density-dependent zero-range pairing force is adopted,

$$V_{pp}(r_1, r_2) = V_0 \frac{1}{2} (1 - P^a) \delta(r_1 - r_2) \left( 1 - \frac{\rho(r_1)}{\rho_{sat}} \right),$$

(8)
with $V_0$ the pairing strength, $\rho_{\text{sat}}$ the saturation density of nuclear matter, and $\frac{1}{2}(1 - P^\sigma)$ projector for the spin $S = 0$ component in the pairing channel. Details of the calculations of pairing tensor and pairing potential can be found in Ref. [73].

For axially deformed nuclei, the potentials in Eqs. (4) and (5) together with densities in Eq. (6) are expanded in terms of the Legendre polynomials [87],

$$f(r) = \sum_\lambda f_\lambda(r) P_\lambda(\cos \theta), \quad \lambda = 0, 2, 4, \cdots,$$

with

$$f_\lambda(r) = \frac{2\lambda + 1}{4\pi} \int d\Omega f(r) P_\lambda(\Omega).$$

Because of the spatial reflection symmetry, $\lambda$ is restricted to be even numbers.

In order to take into account the continuum effects properly, the deformed RHB equations are solved in the Dirac Woods-Saxon basis, in which the radial wave functions have a proper asymptotic behavior for large $r$ [78].

The Dirac Woods-Saxon basis is obtained by solving a Dirac equation with spherical Woods-Saxon scalar and vector potentials [78, 88]. The basis wave function reads

$$\varphi_{n\kappa m}(r) = \frac{1}{r} \begin{pmatrix} iG_{n\kappa}(r)Y^l_{jm}(\Omega_S) \\ -F_{n\kappa}(r)Y^{\tilde{l}}_{jm}(\Omega_S) \end{pmatrix},$$

with $G_{n\kappa}(r)/r$ and $F_{n\kappa}(r)/r$ the radial wave functions for large and small components, and $Y^l_{jm}(\Omega_S)$ the spin spherical harmonics, where $n$ is the radial quantum number, $\kappa = (-1)^{l+l+1/2}(j + 1/2)$, and $\tilde{l} = l + (-1)^{l+l-1/2}$. For the completeness of basis, the solutions in the Dirac sea should also be included in the basis space [78].

With a set of complete Dirac Woods-Saxon basis, solving the RHB equation (2) is equivalent to the diagonalization of RHB matrix. Symmetries can simplify the calculation considerably. For axially deformed nuclei with the spatial reflection symmetry, the parity $\pi$ and the projection of the angular momentum on the symmetry axis $m$ are good quantum numbers. Therefore, the RHB matrix can be decomposed into different $m^\pi$ blocks. Moreover, because of the time-reversal symmetry, one only needs to diagonalize the RHB matrix in each positive-$m$ block,

$$\begin{pmatrix} A - \lambda r & B \\ B^\dagger & -A^* + \lambda r \end{pmatrix} \begin{pmatrix} U_k \\ V_k \end{pmatrix} = E_k \begin{pmatrix} U_k \\ V_k \end{pmatrix},$$

with $A = V^{-1}C$, $B = V^{-1}C^\dagger$, and $C = \begin{pmatrix} V_{00} & V_{01} \\ V_{10} & V_{11} \end{pmatrix}$. The details are given in Ref. [73].
where the matrix elements are

\[ \mathcal{A} = (h^{(m)}_{D(n\kappa)(n'\kappa')}) = \langle n\kappa m | h_D | n'\kappa' m \rangle, \]  

(13)

\[ \mathcal{B} = (\Delta^{(m)}_{(n\kappa)(n'\kappa')}) = \langle n\kappa m | \Delta | n'\kappa' m \rangle. \]  

(14)

The details of the calculation of RHB matrix elements can be found in Ref. [73]. The obtained eigenvectors correspond to the expansion coefficients of quasiparticle wave functions in the Dirac Woods-Saxon basis

\[ \mathcal{U}_k = (u^{(m)}_{k,(n\kappa)}), \quad \mathcal{V}_k = (v^{(m)}_{k,(n\kappa)}). \]  

(15)

From these quasiparticle wave functions, new densities and potentials can be obtained, which are iterated in the RHB equations until the convergence is achieved.

Finally, one can calculate the total energy of a nucleus by [1, 61]

\[ E_{\text{RHB}} = \sum_{k>0} (\lambda_k - E_k) v^2_k - E_{\text{pair}} \]

\[ - \int d^3r \left( \frac{1}{2} \alpha_S \rho_S^2 + \frac{1}{2} \alpha_V \rho_V^2 + \frac{1}{2} \alpha_{TV} \rho_{3}^2 \right. \]

\[ + \frac{2}{3} \beta_S \rho_S^3 + \frac{3}{4} \gamma_S \rho_S^4 + \frac{3}{4} \gamma_V \rho_V^4 + \frac{1}{2} \delta_S \rho_S \Delta \rho_S \]

\[ + \frac{1}{2} \delta_V \rho_V \Delta \rho_V + \frac{1}{2} \delta_{TV} \rho_3 \Delta \rho_3 + \frac{1}{2} \rho_p e A^0 \]

\[ + E_{\text{c.m.}}, \]

(16)

where

\[ v^2_k = \int d^3r \mathcal{V}_k^\dagger(r) \mathcal{V}_k(r). \]  

(17)

For the zero-range pairing force, the pairing field \( \Delta(r) \) is local, and the pairing energy is calculated as

\[ E_{\text{pair}} = -\frac{1}{2} \int d^3r \kappa(r) \Delta(r). \]  

(18)

The center-of-mass (c.m.) correction energy is calculated microscopically,

\[ E_{\text{c.m.}} = -\frac{1}{2mA} \langle \hat{P}^2 \rangle, \]  

(19)

with \( A \) the mass number and \( \hat{P} = \sum_i^A \hat{p}_i \) the total momentum in the c.m. frame. It has been shown that the microscopic c.m. correction provides more reasonable and reliable results than phenomenological ones [89–91].

For deformed nuclei, as the rotational symmetry is broken in the mean-field approximation, the rotational correction energy, i.e., the energy gained by the restoration of rotational
symmetry, should also be included properly [69]. Here the rotational correction energy is obtained from the cranking approximation,

$$E_{\text{rot}} = -\frac{1}{2} \mathcal{J} \langle \hat{J}^2 \rangle,$$

(20)

where \( \mathcal{J} \) is the moment of inertia calculated by the Inglis-Belyaev formula [79] and \( \hat{J} = \sum_i \hat{j}_i \) is the total angular momentum.

The root-mean-square (rms) radius is calculated as

$$R_{\tau, \text{rms}} = \langle r^2 \rangle^{1/2} = \sqrt{\int d^3r [r^2 \rho_\tau(r)]}.$$

(21)

where \( \tau \) represents the proton, the neutron or the nucleon, and \( \rho_\tau \) is the corresponding normalized vector density. The rms charge radius is simply calculated as

$$R_{\text{ch}} = \sqrt{R_{\rho, \text{rms}}^2 + 0.64 \text{ fm}^2}. $$

(22)

The intrinsic quadrupole moment is calculated by

$$Q_{\tau, 2} = \sqrt{\frac{16\pi}{5} \langle r^2 Y_{20}(\theta, \varphi) \rangle}.$$

(23)

The quadrupole deformation parameter is obtained from the quadrupole moment by

$$\beta_{\tau, 2} = \frac{\sqrt{5\pi} Q_{\tau, 2}}{3N_\tau \langle r^2 \rangle},$$

(24)

where \( N_\tau \) refers to the number of neutrons, protons, or nucleons.

The canonical basis \( |\psi_i\rangle \) can be obtained by diagonalizing the density matrix \( \hat{\rho} \) [79],

$$\hat{\rho} |\psi_i\rangle = v_i^2 |\psi_i\rangle,$$

(25)

where the eigenvalue \( v_i^2 \) is the corresponding occupation probability of \( |\psi_i\rangle \). It has to be emphasized that, in a diagonalization problem, the degeneration of eigenvalues will lead to an arbitrary mixture of the eigenvectors that satisfies the unitary transformation in the corresponding subspace. As a consequence, the canonical states are not uniquely defined when their occupation probabilities are degenerate. The problem can be solved by diagonalizing \( \hat{h} \) in the subspace with degenerate occupation probabilities to determine the canonical single-particle states uniquely [1].
III. NUMERICAL DETAILS

Here we concentrate on the numerical details in the systematic calculations for even-even nuclei from the proton drip lines to the neutron drip lines in the nuclear chart with the DRHBc theory. For the particle-hole channel, the relativistic density functional PC-PK1 [69], which has turned out to be very successful in providing good descriptions of the isospin dependence of the binding energy along both the isotopic and the isotonic chain [25, 26, 92], is adopted. For the particle-particle channel, the density-dependent zero-range pairing force in Eq. (8) is used.

In the DRHBc theory, the relativistic Hartree-Bogoliubov equations are solved by the expansion on the Dirac Woods-Saxon basis [78]. Therefore, the box size $R_{\text{box}}$ and the mesh size $\Delta r$ for the Dirac Woods-Saxon basis should be determined. Secondly, for the completeness of basis space, an angular momentum cutoff $J_{\text{max}}$, an energy cutoff $E_{\text{cut}}^+$ for the Woods-Saxon basis in the Fermi sea, and the number of states in the Dirac sea should be chosen properly. Thirdly, the convergence of Legendre expansion in Eq. (9) for the deformed densities and potentials should be guaranteed. Finally, the pairing strength in Eq. (8) should be justified properly.

In Ref. [78], the solutions of Dirac equations in the Dirac Woods-Saxon basis with $R_{\text{box}} = 20$ fm and $\Delta r = 0.1$ fm reproduce accurately the results obtained by the shooting method. In the RCHB mass table [12], $R_{\text{box}} = 20$ fm and $\Delta r = 0.1$ fm have been chosen. Here we have further checked the convergence of DRHBc solutions with respect to $R_{\text{box}}$ and $\Delta r$ for deformed nuclei $^{20}$Ne, $^{112}$Mo, and $^{300}$Th, and found that $R_{\text{box}} = 20$ fm and $\Delta r = 0.1$ fm lead to a satisfactory accuracy of less than 0.01% of the binding energies. Therefore, the box size $R_{\text{box}} = 20$ fm and the mesh size $\Delta r = 0.1$ fm are used in the present DRHBc calculations.

In the following, numerical checks for the energy cutoff $E_{\text{cut}}^+$ and the angular momentum cutoff $J_{\text{max}}$ will be performed. The number of states in the Dirac sea is taken to be the same as that in the Fermi sea [72, 73, 78]. Convergence check for the Legendre expansion will also be performed. In addition, the pairing strength will be determined by reproducing experimental odd-even mass differences, and the strategy to determine ground states in the DRHBc calculations will be suggested according to the self-consistency between unconstrained and constrained calculations.
A. Energy cutoff for Woods-Saxon basis

![Graph showing total energy as a function of the energy cutoff \( E^+_{\text{cut}} \) for doubly-magic nuclei \(^{40}\text{Ca}\) (a), \(^{100}\text{Sn}\) (b), and \(^{208}\text{Pb}\) (c) calculated by the DRHBc theory. Dashed lines show total energies of these three nuclei in the RCHB mass table [12]. Same as the RCHB calculations [12], the angular momentum cutoff \( J_{\text{max}} = 19/2 \hbar \) is used here.]

FIG. 1: Total energy as a function of the energy cutoff \( E^+_{\text{cut}} \) for doubly-magic nuclei \(^{40}\text{Ca}\) (a), \(^{100}\text{Sn}\) (b), and \(^{208}\text{Pb}\) (c) calculated by the DRHBc theory. Dashed lines show total energies of these three nuclei in the RCHB mass table [12]. Same as the RCHB calculations [12], the angular momentum cutoff \( J_{\text{max}} = 19/2 \hbar \) is used here.

In Ref. [78], it is found that the results of the calculations with the Dirac Woods-Saxon basis converge to the exact ones with the energy cutoff \( E^+_{\text{cut}} \sim 300 \) MeV. Here we perform the fully self-consistent calculations to examine the convergence of total energy with the energy cutoff \( E^+_{\text{cut}} \), as seen in Fig. 1, for doubly-magic nuclei \(^{40}\text{Ca}\), \(^{100}\text{Sn}\), and \(^{208}\text{Pb}\). The results from the RCHB mass table [12] are also shown for comparison. The total energy of each nucleus converges gradually to the corresponding RCHB result with the increasing
When \( E_{\text{cut}}^+ = 300 \text{ MeV} \), the total energy differences between the DRHBc and RCHB calculations for \(^{40}\text{Ca}\), \(^{100}\text{Sn}\), and \(^{208}\text{Pb}\) are 0.0097 MeV, 0.0193 MeV, and 0.0179 MeV, respectively. Changing \( E_{\text{cut}}^+ \) from 300 MeV to 350 MeV, the total energy varies by 0.0037 MeV, 0.0090 MeV, and 0.0093 MeV for \(^{40}\text{Ca}\), \(^{100}\text{Sn}\), and \(^{208}\text{Pb}\), respectively. Therefore, in consistent with the conclusion in Ref. [78] and the RCHB mass table [12], \( E_{\text{cut}}^+ = 300 \text{ MeV} \) is a reasonable choice for the DRHBc mass table calculations.

B. Angular momentum cutoff

![Graph showing total energy and deformation versus angular momentum cutoff](image)

**FIG. 2:** Total energy and deformation versus the angular momentum cutoff \( J_{\text{max}} \) for deformed nuclei \(^{20}\text{Ne}\) (a), \(^{112}\text{Mo}\) (b), and \(^{300}\text{Th}\) (c), with the energy cutoff \( E_{\text{cut}}^+ = 300 \text{ MeV} \). Here the pairing correlation is neglected.

In the RCHB mass table calculations, the convergence has been confirmed for the an-
angular momentum cutoff $J_{\text{max}} = 19/2 \hbar$ [12]. With deformation effects included in DRHBc calculations, further numerical checks for $J_{\text{max}}$ are necessary.

Figure 2 shows the total energy and deformation versus the angular momentum cutoff $J_{\text{max}}$ for deformed nuclei $^{20}$Ne, $^{112}$Mo, and $^{300}$Th, where $E_{\text{cut}}^+ = 300$ MeV and the pairing is neglected. The stable light nucleus $^{20}$Ne, short-lived medium-heavy nucleus $^{112}$Mo, and neutron-rich heavy nucleus $^{300}$Th are chosen in order to determine a universal angular momentum cutoff. It is found that $J_{\text{max}} = 19/2 \hbar$ is enough for light nuclei like $^{20}$Ne and medium-heavy nuclei like $^{112}$Mo. For heavy nucleus $^{300}$Th, changing $J_{\text{max}}$ from $19/2 \hbar$ to $27/2 \hbar$, the deformation varies by about 0.08 and the total energy varies by 4.0406 MeV. Changing $J_{\text{max}}$ from $23/2 \hbar$ to $27/2 \hbar$, the deformation varies by about 0.002 and the total energy varies by 0.2180 MeV, which is about 0.01% of its total energy. Therefore, a unified angular momentum cutoff $J_{\text{max}} = 23/2 \hbar$ is suggested in the DRHBc calculations in order to achieve a satisfactory accuracy for the entire nuclear landscape.

C. Legendre expansion

In the DRHBc theory, the deformed densities and potentials are expanded in terms of the Legendre polynomials as in Eq. (9) [72]. Since a nucleus with a large deformation may need higher orders in the Legendre expansion, the convergence of the expansion truncation $\lambda_{\text{max}}$ is checked for nuclei $^{20}$Ne, $^{112}$Mo, and $^{300}$Th at the constrained deformation $\beta_2 = 0.6$. Figure 3 shows the total energies as a function of the Legendre expansion truncation $\lambda_{\text{max}}$ for $^{20}$Ne, $^{112}$Mo, and $^{300}$Th. Changing $\lambda_{\text{max}}$ from 6 to 16, the total energy varies by 0.03 MeV for $^{20}$Ne and 0.05 MeV for $^{112}$Mo, i.e., less than 0.03% of their total energies. Changing $\lambda_{\text{max}}$ from 8 to 16, the total energy of $^{300}$Th varies by 0.16 MeV, i.e., less than 0.01% of its total energy. Therefore, in the mass table calculations, for light nuclei like $^{20}$Ne and medium-heavy nuclei like $^{112}$Mo, $\lambda_{\text{max}} = 6$ can provide converged results. For heavy nuclei like $^{300}$Th, $\lambda_{\text{max}} = 8$ is necessary in order to achieve convergence. Although the pairing correlation is neglected, the conclusion is also valid after the inclusion of the pairing correlation [93].
FIG. 3: Total energy as a function of the Legendre expansion truncation $\lambda_{\text{max}}$ for nuclei $^{20}\text{Ne}$ (a), $^{112}\text{Mo}$ (b), and $^{300}\text{Th}$ (c) from constrained DRHBc calculations at the quadrupole deformation $\beta_2 = 0.6$, with the energy cutoff $E_{\text{cut}}^+ = 300$ MeV and the angular momentum cutoff $J_{\text{max}} = 23/2 \hbar$. Here the pairing correlation is neglected.

D. Pairing strength

In the present DRHBc calculations, the saturation density $\rho_{\text{sat}} = 0.152$ fm$^{-3}$ in Eq. (8) and the sharp pairing window of 100 MeV are used. With the angular momentum cutoff $J_{\text{max}} = 23/2 \hbar$, the pairing strength is chosen to reproduce the experimental odd-even mass differences,

$$\Delta^{(3)} = \frac{(-1)^N}{2} [E_b(Z, N + 1) - 2E_b(Z, N) + E_b(Z, N - 1)].$$  \hspace{1cm} (26)

The odd-even mass differences in Ca and Pb isotopic chains are used to fix the pairing strength. As Ca and Pb isotopes are spherical, the results from the DRHBc theory are the
same as those from the RCHB theory.

FIG. 4: Odd-even mass differences of Ca (a) and Pb (b) isotopic chains in the DRHBc calculations versus the mass number, for $V_0 = -342.5$ MeV fm$^3$ with $J_{\text{max}} = 23/2 \hbar$ (inverted triangle) and for $V_0 = -325.0$ MeV fm$^3$ with $J_{\text{max}} = 23/2 \hbar$ (circle). The corresponding experimental data [15] (square) and the results in the RCHB mass table [12] (triangle) are shown for comparison.

Figure 4 shows the DRHBc calculated odd-even mass differences for Ca isotopes and Pb isotopes, the corresponding experimental data [15], as well as the results in the RCHB mass table [12]. For $J_{\text{max}} = 23/2 \hbar$, if the pairing strength $V_0 = -342.5$ MeV fm$^3$ in Ref. [12] is adopted, the odd-even mass differences will be overestimated for most of Ca and Pb isotopes. In order to reproduce the experimental values, $V_0 = -325.0$ MeV fm$^3$ should be adopted. Therefore, the pairing strength $V_0 = -325.0$ MeV fm$^3$ will be used in the DRHBc mass table calculations.
E. Constrained calculations

In order to describe the shape of the atomic nucleus and understand the shape coexistence, it is crucial to obtain the potential energy surface (PES) of the nucleus as a function of the deformation \[33\]. In microscopic models, there are two different ways to obtain the PES, i.e., the adiabatic and configuration-fixed (diabatic) approaches \[94–98\]. In the present DRHBc calculations, the adiabatic constrained calculation is adopted to obtain the potential energy curve (PEC) of the nucleus as a function of the quadrupole deformation and the augmented Lagrangian method \[99\] is used.

For each nucleus, in order to find the ground state, the DRHBc calculations are performed with initial deformations \(\beta_2 = -0.4, -0.2, 0.0, 0.2, 0.4, \) and 0.6. The solution with the lowest total energy corresponds to the ground state. Sometimes the constrained calculation is also necessary if the PEC is very soft, or several local minima are close to each other.

![FIG. 5: Potential energy curve (PEC) of \(^{130}\)Nd in constrained DRHBc calculations. The unconstrained results are also shown. Here the energy cutoff \(E_{\text{cut}}^+ = 300\) MeV, the angular momentum cutoff \(J_{\text{max}} = 23/2\ \hbar\), the Legendre expansion truncation \(\lambda_{\text{max}} = 6\), and the pairing strength \(V_0 = -325.0\) MeV fm\(^3\) are used.](image)

Taking \(^{130}\)Nd as an example, the unconstrained calculations with different initial deformations respectively converge to \(\beta_2 = -0.27, 0.00, \) and 0.43, as shown in Fig. 5. The
prolate solution has the lowest total energy and thus is considered to be the ground state. The constrained calculations are further performed for $^{130}$Nd and shown in Fig. 5. Both the unconstrained prolate and oblate solutions correspond to the local minima in the PEC. Although the solution at $\beta_2 = 0.00$ is not a local minimum, the calculated total energy agrees with the constrained one. The self-consistency is therefore guaranteed and the strategy to find the ground state from unconstrained calculations is reasonable and practicable. Of course, whenever necessary, constrained calculations can be performed to build the PEC and confirm the ground state.

Summarizing the above discussions, the numerical details for the DRHBc mass table calculations including the box size $R_{\text{box}} = 20$ fm, the mesh size $\Delta r = 0.1$ fm, the energy cutoff $E_{\text{cut}}^+ = 300$ MeV, the angular momentum cutoff $J_{\text{max}} = 23/2 \hbar$, the pairing strength $V_0 = -325.0$ MeV fm$^3$, and the sharp pairing window of 100 MeV are suggested. For Legendre expansion, the expansion truncation $\lambda_{\text{max}} = 6$ is suggested for $Z \leq 80$, and $\lambda_{\text{max}} = 8$ is suggested for $Z > 80$.

IV. RESULTS AND DISCUSSION

Taking even-even Nd isotopes as examples, the DRHBc calculations with the suggested numerical details in Sec. III are performed and the ground-state properties, such as binding energy, two-neutron separation energy, Fermi energy, quadrupole deformation, rms radius, density distribution, as well as the single-particle levels are obtained. In this section, ground-state properties of Nd isotopes will be discussed and compared with those predicted by the RCHB theory [12] and with data available [15, 80, 81]. The ground-state properties of even-even Nd isotopes are also tabulated in Appendix A.

A. Binding energy

In Fig. 6, the binding energies per nucleon for neodymium isotopes from the DRHBc calculations are shown versus the neutron number together with the RCHB results [12] and data available [15]. The most stable nucleus $^{142}$Nd in neodymium isotopes with the magic number $N = 82$ is well reproduced by the DRHBc theory. Distinguishable differences
FIG. 6: Binding energy per nucleon of Nd isotopes from the DRHBc calculations as a function of the neutron number. The results in the RCHB mass table [12] and the experimental data from Ref. [15] are shown for comparison.

between the DRHBc and the RCHB calculations can be seen. Away from the neutron shell closures 82 and 126, the deformation effects in the DRHBc calculations improve the RCHB results and reproduce better the data.

Figure 7 shows the differences between calculated binding energies and the data available [15]. The deformation effects in the DRHBc calculations dramatically reduce the deviation between the RCHB calculations and the data from up to 13.8 MeV to less than 3.8 MeV. The rms deviation for the binding energy is reduced from 8.301 MeV in the RCHB calculations to 2.668 MeV in the DRHBc ones.

Following Ref. [69], the differences after including rotational correction energies in Eq. (20) in the DRHBc theory are also shown in Fig. 7. The largest deviation becomes less than 1.7 MeV and the rms deviation is reduced to 0.958 MeV. It should be noted that the collective Hamiltonian method to better estimate the beyond-mean-field correlation energies is suggested in Ref. [26].
FIG. 7: The difference between the experimental binding energy \[15\] and the DRHBc calculations for Nd isotopes versus the neutron number. The results of the DRHBc calculations including rotational correction and the RCHB mass table \[12\] are also shown for comparison.

FIG. 8: Two-neutron separation energy as a function of the neutron number for Nd isotopes in the DRHBc calculations. The RCHB results \[12\] and the data available \[15\] are also shown for comparison.
B. Two-neutron separation energy

From binding energies, the two-neutron separation energy can be calculated and the neutron drip line can be decided. Figure 8 shows the DRHBc and RCHB calculated two-neutron separation energies of neodymium isotopes, in comparison with the existing experimental data [15]. The DRHBc results are consistent with the RCHB ones for spherical nuclei near the neutron magic numbers $N = 82$ and $N = 126$. From $^{132}$Nd to $^{140}$Nd and $^{146}$Nd to $^{156}$Nd, the DRHBc calculations including deformation effects reproduce better the experimental values. From the DRHBc calculated two-neutron separation energies, the neutron drip-line (last bound) nucleus is predicted to be $^{214}$Nd, while it is $^{228}$Nd in the RCHB theory [12]. Including the deformation degrees of freedom, the predicted neutron drip-line location varies by 14 neutrons. It is an interesting topic to investigate the deformation effects on the verge of whole nuclear landscape.

C. Fermi energy

In addition to the two-neutron separation energy, the Fermi energy can also provide information about the nucleon drip line. Figure 9 shows the neutron and proton Fermi energies in the DRHBc calculations, in comparison with the RCHB results [12]. If the pairing energy vanishes, the Fermi energy is chosen to be the energy of the last occupied single-particle state. In Fig. 9(a), the neutron Fermi energy becomes positive at $^{218}$Nd and $^{230}$Nd in the RCHB ones. In the DRHBc calculations, although the neutron Fermi energy for $^{216}$Nd is negative with $\lambda_n = -0.025$ MeV, it is unstable against neutron emission with $S_{2n} = -0.057$ MeV in Fig. 8. In the RCHB calculations, the neutron drip line from the Fermi energy is consistent with the two-neutron separation energies. The sudden increases in the neutron Fermi energy reflect the shell closures at $N = 82$ and $N = 126$. In Fig. 9(b), the proton Fermi energy becomes positive at $^{118}$Nd in the DRHBc calculations and $^{124}$Nd in the RCHB ones. Therefore, the deformation effects influence not only the neutron but also the proton drip line for neodymium isotopes. Near $N = 82$ and 126, the Fermi energies in the DRHBc calculations agree more or less with the RCHB ones. Moving away from the shell closures, the smooth evolution of Fermi energy does not exist in the DRHBc calculations due to deformation effects.
FIG. 9: Neutron (a) and proton (b) Fermi energies for Nd isotopes in the DRHBc calculations versus the neutron number. The results from the RCHB mass table [12] are shown for comparison.

D. Quadrupole deformation

The ground-state quadrupole deformation parameters in Eq. (24) in the DRHBc calculations for neodymium isotopes are shown in Fig. 10 and compared with the available data [80]. Generally, the DRHBc calculated ground-state quadrupole deformations reproduce well the data. The nuclei near $N = 82$ and $N = 126$ exhibit the spherical shape due to the shell effects. For these nuclei, the bulk properties in the DRHBc calculations discussed above are consistent with the RCHB ones. The shape evolution is following, a) from the proton drip line to $N = 80$, the shape changes from prolate to spherical; b) from $N = 84$ to $N = 122$, the shape changes from spherical to prolate and then back to spherical; c) from $N = 130$ to $N = 138$, the shape changes from spherical to prolate; d) from $N = 140$ to the neutron drip line, the shape changes to oblate.
FIG. 10: Quadrupole deformation as a function of the neutron number in the DRHBc calculations for Nd isotopes. The data available [80] are shown for comparison.

E. Rms radii

In Fig. 11(a), the charge radius as a function of the neutron number in the DRHBc calculations for neodymium isotopes are shown, together with the RCHB results [12] and the available data [81]. In general, the data are reproduced well by both the RCHB and DRHBc calculations. In particular, the DRHBc calculations reproduce well not only the data from $^{134}$Nd to $^{148}$Nd but also the kink at $^{142}$Nd, in which the deformation plays a crucial role. For $^{132}$Nd and $^{150}$Nd, the charge radii are underestimated by the RCHB calculations due to the neglect of deformation, and are slightly overestimated by the DRHBc ones due to the overestimated deformation in Fig. 10. The overestimation of deformation for $^{132}$Nd and $^{150}$Nd might be due to their soft PESs shown in Refs. [100, 101].

In Fig. 11(b), the rms neutron radii $R_n$, proton radii $R_p$, and matter radii $R_m$ in the DRHBc calculations for neodymium isotopes are shown. The empirical matter radii $r_0A^{1/3}$ with $r_0$ determined by the most stable neodymium isotope $^{142}$Nd are shown to guide the eye. Starting from the proton drip line, $R_n$, $R_p$, and $R_m$ are close to each other and gradually increase with the neutron number. There is a sudden decrease from $^{132}$Nd to $^{134}$Nd because the quadrupole deformation parameter $\beta_2$ decreases from 0.46 to 0.23. Beyond $^{134}$Nd, the proton radius increases gradually, the neutron radius increases more rapidly, and the matter
FIG. 11: (a) Charge radius as a function of the neutron number in the DRHBc calculations for Nd isotopes. The results in the RCHB mass table [12] and existing data from Ref. [81] are shown for comparison. (b) Rms neutron radius, proton radius, and matter radius as functions of the neutron number in the DRHBc calculations for Nd isotopes. The empirical matter radii $r_0 A^{1/3}$, in which $r_0 = 0.948 \text{ fm}$ determined by $^{142}\text{Nd}$, are also shown to guide the eye.

radius is in between. By scaling the empirical matter radius $r_0 A^{1/3}$ by the most stable nucleus $^{142}\text{Nd}$, for the nuclei far away from the stability line, the calculated radii are systematically larger than the empirical ones. In particular, for nuclei with $N > 126$, the ever increasing deviation from the empirical value may indicate some underlying exotic structure.

F. Neutron density distribution

Figure 12 shows neutron density profiles of selected even-even neodymium isotopes $^{124,134,\ldots,214}\text{Nd}$. In Fig. 12(a), $\rho_{n,0}$ represents the spherical component of the neutron density...
FIG. 12: (a) Spherical component of the neutron density distribution, (b) the neutron density distribution along the symmetry axis $z$, and (c) the neutron density distribution perpendicular to the symmetry axis with $r_\perp = \sqrt{x^2 + y^2}$, for selected even-even neodymium isotopes $^{124,134,\cdots,214}$Nd in the DRHBc calculations.
distribution [cf. Eq. (9)]. In Figs. 12(b) and 12(c), the density distributions along ($\theta = 0^\circ$) and perpendicular ($\theta = 90^\circ$) to the symmetry axis $z$ are shown, respectively. In Fig. 12(a), for the spherical component, the neutron density distribution becomes more diffuse monotonically with the increasing mass number. In Figs. 12(b) and 12(c), the neutron density distributions manifest not only the diffuseness with the increasing neutron number but also the deformation effects. In Fig. 12(b), although $^{134}$Nd has ten more neutrons than $^{124}$Nd, its density along the symmetry axis is smaller than that of $^{124}$Nd for $z \gtrsim 6$ fm. This can be understood from the deformation $\beta_2 = 0.41$ for $^{124}$Nd and $\beta_2 = 0.23$ for $^{134}$Nd. The density with a larger prolate deformation is more elongated along the symmetry axis and leads to a more diffused density distribution. Due to the oblate deformation, the density distributions for the most neutron-rich $^{204}$Nd and $^{214}$Nd are not the most diffused ones. In Fig. 12(c), since the deformation for $^{124,134,\ldots,194}$Nd is either spherical or prolate, its density distribution perpendicular to the symmetry axis is equal to or smaller than that along the symmetry axis. The densities for oblate $^{204}$Nd and $^{214}$Nd are much more elongated perpendicular to the symmetry axis and lead to significantly larger density distributions along $r_\perp$.

G. Single-neutron levels

The single-neutron spectrum around the neutron Fermi energy $\lambda_n$ in the canonical basis for $^{214}$Nd is shown in Fig. 13. As the projection of the angular momentum on the symmetry axis $m$ and the parity $\pi$ are good quantum numbers in the axially deformed system with the spatial reflection symmetry, each state is labeled with $m^\pi$. The main components in the spherical Woods-Saxon basis and rms radii for the states with single-neutron energies higher than $-0.3$ MeV are also given. The lengths of horizontal lines represent the occupation probabilities $v^2$ in Fig. 13. The occupation probabilities calculated by the BCS formula [79] with the average pairing gap and single-neutron energies in canonical basis is shown by the dashed line. The bound single-neutron levels are occupied with considerable probabilities, and those with single-neutron energies smaller than $-1$ MeV are almost fully occupied. As the neutron Fermi energy $\lambda_n = -0.07$ MeV and is close to the threshold, the states in continuum have noticeable occupation probabilities due to the pairing correlation. Since the neutron Fermi energy is negative, the single-neutron densities in continuum are localized [83] and the nucleus is still bound. The occupation probabilities of both bound states and
FIG. 13: Single-neutron levels around the Fermi energy in the canonical basis for $^{214}$Nd versus the occupation probability $\nu^2$ in the DRHBc calculations. Each level is labeled by the quantum numbers $m^\pi$. The main components and rms radii for the levels with $\epsilon > -0.3$ MeV are also given. The neutron Fermi energy $\lambda_n$ is shown with the dotted line. The occupation probability from the BCS formula with the average pairing gap is given by dashed line. The thin solid line represents the continuum threshold.

Continuum states are roughly consistent with those calculated by BCS formula. By summing the number of neutrons in the continuum, one obtains about 4 neutrons in the continuum, which could be related to the possible neutron halo phenomenon [60, 62–64, 72, 73, 102]. The states whose main components are $s$ waves or $d$ waves with low centrifugal barriers have relatively larger rms radii, and are helpful in the formation of halos. It can also be seen in Fig. 12 that, $^{214}$Nd has significant density distributions in the region of large $r$, which could be an indicator of exotic structure such as the existence of the neutron halo. This could be also an interesting topic worth further studying and the strategy in Refs. [72, 73] can be
employed to investigate such exotic structure.

H. Neutron skin and proton radioactivity

In order to explore the possible exotic structures in Nd isotopes, the thickness of the neutron skin, the particles number in the continuum, contributions of different states to the total density, and the proton radioactivity are investigated and discussed in detail.

FIG. 14: (a) Thickness of the neutron skin \( r_n - r_p \) together with its increasing trend for \( N \leq 126 \) as a dashed line, and (b) the number of particles in the continuum \( N_c \), two-neutron separation energy \( S_{2n} \), and two times the negative neutron Fermi energy \( -2\lambda_n \) as functions of the neutron number for neutron-rich neodymium isotopes with \( N \geq 120 \) in the DRHBc calculations.

Figure 14(a) shows the thickness of the neutron skin \( r_n - r_p \) for Nd isotopes with \( N \geq 120 \). The thickness of the neutron skin increases gradually from \( N = 120 \) to \( N = 126 \) and significantly after the neutron shell closure \( N = 126 \), and reaches the maximum at the neutron drip-line nucleus \( ^{214}\text{Nd} \).

In Fig. 14(b), the number of particles in the continuum \( N_c \), the two-neutron separation...
energy $S_{2n}$, and two times the negative neutron Fermi energy $-2\lambda_n$ for Nd isotopes with $N \geq 120$ are shown. The relation $S_{2n} \approx -2\lambda_n$ is reproduced except for $^{180}$Nd due to the pairing collapse and $^{192,200}$Nd due to the change of deformation (configuration). For the nuclei with $N > 126$, the neutron Fermi energy is close to the continuum threshold ($\lambda_n > -1$ MeV), as a result neutrons can be scattered into the continuum due to the pairing correlation [61, 83]. The sudden increase of $N_c$ and the sudden decrease of $S_{2n}$ after $N = 126$ in Fig. 14(b) coincide with the abrupt change in the thickness of neutron skin $r_n - r_p$ in Fig. 14(a). The nuclei with more than 2 neutrons in the continuum, $^{188}$Nd, $^{190}$Nd, $^{212}$Nd, and $^{214}$Nd, have the smallest two-neutron separation energies.

Since for $^{214}$Nd, there are more than 4 neutrons in the continuum, and the two-neutron separation energy is less than 0.1 MeV, and the thickness of the neutron skin $r_n - r_p$ is around 0.9 fm, it is encouraging to investigate its density distribution to explore the existence of possible neutron skin or neutron halo.

In Fig. 15(a), the neutron and proton density distributions for $^{214}$Nd are shown. Both the neutron and proton density distributions show oblate shapes, in consistent with Fig. 10. Owing to the large neutron excess, the neutron density extends much farther than the proton.

According to the single-particle levels in Fig. 13, there is a gap between the levels with $\epsilon < -1.2$ MeV and those with $\epsilon > -0.3$ MeV. Following the strategy in Refs. [72, 73], the neutron density is decomposed into two parts as shown in Figs. 15(b) for $\epsilon < -1.2$ MeV and 15(c) for $\epsilon > -0.3$ MeV. The quadrupole deformations are respectively $\beta_2 = -0.268$ for $\epsilon < -1.2$ MeV in Fig. 15(b) and $\beta_2 = -0.160$ for $\epsilon > -0.3$ MeV in Fig. 15(c). While both are oblate, they are still slightly decoupled. Although the density in Fig. 15(c) is contributed by the weakly bound states and continuum, it is less diffuse than that in Fig. 15(b) both along and perpendicular to the symmetry axis.

Similarly, the neutron density can be decomposed into the part for bound states with $\epsilon < 0$ MeV in Fig. 15(d), and the part for continuum with $\epsilon > 0$ MeV in Fig. 15(e). The difference between such decomposition and the previous one is the allocation of the weakly bound state $13/2^-$, which corresponds to an oblate shape and the main component $1j_{15/2}$ with a mixing of $|Y_{76}(\theta, \varphi)|^2$ and $|Y_{77}(\theta, \varphi)|^2$. This allocation hardly influences the density distribution in Fig. 15(b) and the quadrupole deformation changes slightly to $\beta_2 = -0.273$ in Fig. 15(d). In contrast, the density distribution changes from oblate with $\beta_2 = -0.160$
FIG. 15: Density distributions with $z$ axis as the symmetry axis in $^{214}\text{Nd}$ for (a) the proton (for $x < 0$) and the neutron (for $x > 0$), and the neutron with single-particle energy (b) $\epsilon < -1.2$ MeV, (c) $\epsilon > -0.3$ MeV, (d) $\epsilon < 0$ MeV, and (e) $\epsilon > 0$ MeV in the canonical basis. In each plot, a dotted circle is drawn to guide the eye.

in Fig. 15(c) to nearly spherical with $\beta_2 = 0.047$ in Fig. 15(e). The decoupling between the oblate shape contributed by bound states and the nearly spherical one by continuum is remarkable. By comparing Figs. 15(b) and 15(c) or 15(d) and 15(e), there is no clear clue
for a halo structure in $^{214}$Nd.

![Graph](image_url)

**FIG. 16:** Contribution of each single-particle state in the canonical basis to the total neutron density at (a) $\theta = 0^\circ$ (along the symmetry axis) and (b) $\theta = 90^\circ$ (perpendicular to the symmetry axis) in $^{214}$Nd as a function of the radius. The states with significant contributions ($\gtrsim 0.1$) in the asymptotic area are highlighted and their energies and main components are given.

In order to further identify the nature of neutron halo or neutron skin in $^{214}$Nd, the contribution of each single-particle state in the canonical basis to the total neutron density is shown in Fig. 16. Along the symmetry axis, the state $1/2^{-}$ with $\epsilon = -2.69$ MeV plays the dominant role for large $r$ as shown in Fig. 16(a). Another $1/2^{-}$ state with $\epsilon = -4.06$ MeV also makes distinguishable contributions for large $r$. The contribution of the $1/2^{+}$ state embedded in the continuum becomes more and more important for $r \gtrsim 14$ fm because its main component $s$ wave is free from the centrifugal barrier. Perpendicular to the symmetry axis, several bound states with $\epsilon < -2.6$ MeV together with the $1/2^{+}$ state in the continuum contribute to the total neutron density for large $r$ as shown in Fig. 16(b). The contribution of the $1/2^{+}$ state in the continuum evolves similarly at both $\theta = 0^\circ$ and $90^\circ$ due to its nearly spherical density distribution. From Figs. 16(a) and 16(b), it can be clearly seen that the
density in the region of large \( r \) is mainly contributed by the deeply bound low-\( m \) states with \( \epsilon < -2.6 \) MeV, and the contributions of continuum states except for the \( 1/2^+ \) state are very small because of their centrifugal barriers as shown in Fig. 13, explaining why the density distributions in Figs. 15(b) and 15(d) are more diffused than those in Figs. 15(c) and 15(e). Therefore, the halo character in \(^{214}\text{Nd}\) can be excluded.

On the proton-rich side, possible exotic phenomena include the proton halo and the proton radioactivity. The interest in the proton radioactivity has been boosted significantly by the discoveries of one- and two-proton emission beyond the proton drip lines \([103, 104]\). Comprehensive theoretical efforts have been made to investigate the proton radioactivity based on the CDFT \([71, 105–108]\). Because of its self-consistent treatment of deformation, pairing correlation, and continuum, it is natural to apply the DRHBc theory to study the proton radioactivity to understand the physics beyond drip line.

As shown in Fig. 9(b), the proton drip-line nucleus for Nd isotopes in the DRHBc theory is \(^{120}\text{Nd}\). The proton Fermi energies for \(^{118}\text{Nd}\) and other lighter even-even Nd isotopes are positive, and they might be unstable against the proton emission. However, due to the existence of Coulomb barrier, some of them may become quasi-bound proton emitters with certain half-lives. To explore such exotic phenomena, the single-proton spectrum around the proton Fermi energy \( \lambda_p \) in the canonical basis for \(^{114}\text{Nd}\) is shown in Fig. 17 as an example. The heights of Coulomb barrier along and perpendicular to the symmetry axis are given. \(^{114}\text{Nd}\) is prolate deformed with \( \beta_2 = 0.248 \) and \( \beta_{p,2} = 0.269 \). Accordingly, the height of Coulomb barrier at \( \theta = 0^\circ \) is 9.12 MeV and at \( \theta = 90^\circ \) is 10.05 MeV. For \(^{114}\text{Nd}\), the proton Fermi energy \( \lambda_p = 4.35 \) MeV is below the Coulomb barrier at either \( \theta = 0^\circ \) or \( 90^\circ \). Therefore the protons (\( \approx 8 \)) above the continuum threshold are still quasi-bound by the Coulomb barrier. These protons may undergo quantum tunneling. By comparing the calculated binding energies of \(^{114}\text{Nd}\) and its two-proton emission daughter nucleus \(^{112}\text{Ce}\), one can find the decay energy \( Q_{2p} = -S_{2p} = 8.53 \) MeV is positive and thus the two-proton radioactivity is energetically allowed. Similarly, the decay energies \( Q_{4p} = 14.95 \) MeV, \( Q_{6p} = 19.03 \) MeV, and \( Q_{8p} = 21.17 \) MeV for \(^{114}\text{Nd}\) are obtained by comparing its binding energy with those of its corresponding daughter nuclei, which suggests the possibility of multi-proton radioactivity in \(^{114}\text{Nd}\). Further calculations indicate that \(^{116}\text{Nd}\) and \(^{118}\text{Nd}\) are also candidates for two-proton and even multi-proton radioactivity. Systematical investigation of the proton radioactivity including not only even-even nuclei but also odd mass nuclei and odd-odd nuclei as well as
FIG. 17: Single-proton levels around the Fermi energy in the canonical basis for $^{114}$Nd versus the occupation probability $v^2$. Each level is labeled by the quantum numbers $m^\pi$. The Fermi energy $\lambda_p$ is shown as a dotted line. The continuum threshold is represented by a thin solid line. The shaded areas represent respectively the regions above the Coulomb barrier at 0° (along the symmetry axis) and 90° (perpendicular to the symmetry axis).

the decay half-lives is highly demanded.

V. SUMMARY

In summary, the DRHBc theory based on the point-coupling density functionals including both the deformation and continuum effects is developed. Numerical details towards constructing the DRHBc mass table have been examined. The DRHBc calculation previously accessible only for light nuclei up to magnesium isotopes has been extended for all even-even nuclei in the nuclear chart. Taking even-even neodymium isotopes from the proton drip line
to the neutron drip line as examples, the ground-state properties and exotic structures are investigated.

The numerical details towards constructing the DRHBc mass table for even-even nuclei with satisfactory accuracy have been examined. For the Dirac Woods-Saxon basis, the box size $R_{\text{box}} = 20$ fm, the mesh size $\Delta r = 0.1$ fm, the energy cutoff $E_{\text{cut}}^+ = 300$ MeV, and the angular momentum cutoff $J_{\text{max}} = 23/2 \hbar$ are suggested. For the pairing channel, the pairing strength $V_0 = -325.0$ MeV fm$^3$ and the pairing window of 100 MeV are suggested. For the Legendre expansion of deformed densities and potentials, the expansion truncation $\lambda_{\text{max}} = 6$ is suggested for $Z \leq 80$, and $\lambda_{\text{max}} = 8$ is suggested for $Z > 80$.

Taking even-even neodymium isotopes from the neutron drip line to the proton drip line as examples, the DRHBc calculations with the density functional PC-PK1 are systematically performed. The strategy to locate the ground states is suggested and confirmed by constrained calculations. The ground-state properties for even-even neodymium isotopes thus obtained are compared with available data and the results in the spherical RCHB mass table [12].

The experimental binding energies for even-even neodymium isotopes are reproduced by the DRHBc calculations with a rms deviation of 0.958 MeV with the rotational correction and 2.668 MeV without the rotational correction, in comparison with 8.301 MeV given by the spherical RCHB calculations. Accordingly, the two-neutron separation energies are better reproduced. The predicted proton and neutron drip-line nuclei are respectively $^{120}$Nd and $^{214}$Nd, in contrast with $^{126}$Nd and $^{228}$Nd in the RCHB theory.

The shapes and sizes for even-even neodymium isotopes are correctly reproduced by the DRHBc calculations. Good agreements with the observed quadrupole deformation and its evolution as well as the charge radius and its kink around the shell closure $N = 82$ are obtained.

The neutron density distributions for neodymium isotopic chain are examined. It is found that their spherical components increase with the mass number monotonically. The density distribution of a prolate deformed nucleus is more diffused along the symmetry axis, and an oblate deformed one is more diffused perpendicular to the symmetry axis.

For the most neutron-rich neodymium isotope $^{214}$Nd, its two-neutron separation energy is smaller than 0.1 MeV, its neutron skin thickness is around 0.9 fm, and there are more than 4 neutrons in continuum. By decomposing the neutron density of $^{214}$Nd, an interesting
decoupling between the oblate shape $\beta_2 = -0.273$ contributed by bound states and the nearly spherical one $\beta_2 = 0.047$ contributed by continuum is found. Contributions of different single-particle states to the total neutron density show that, the neutron density in the region of large $r$ is mainly contributed by the deeply bound low-$m$ states with $\epsilon < -2.6$ MeV. Therefore, the exotic character in $^{214}$Nd is concluded as neutron skin instead of halo.

For the proton-rich side, by examining the proton single-particle energies, the Fermi energy, and the Coulomb barrier for $^{114}$Nd beyond the proton drip line, possible two-proton and even multi-proton emissions are predicted. Further calculations show that $^{116}$Nd and $^{118}$Nd are also candidates for two-proton and even multi-proton radioactivity. Future investigation of the proton radioactivity including not only even-even nuclei but also odd mass nuclei and odd-odd nuclei as well as the decay half-lives is highly demanded.
