ABSTRACT

Introduction: Recurrent metastatic choriocarcinoma is a rare disease with historically limited guidance in the literature regarding standardized treatment protocols. In this case report, we review the course of a patient with recurrent metastatic choriocarcinoma re-treated with single agent pembrolizumab.

Our patient was initially diagnosed with metastatic choriocarcinoma (FIGO Stage IV, WHO Score 13) after presenting for evaluation of amenorrhea. She received standard treatment with etoposide, methotrexate, actinomycin D, cyclophosphamide and vincristine (EMA-CO), with a complete response. However, she recurred one year later. Molecular profiling of a chest wall tumor demonstrated strong expression of programmed cell death ligand 1 (PD-L1), and she was started on treatment with single agent pembrolizumab achieving a complete response. Unfortunately, she recurred again 6 months following completion of treatment. She was re-treated with pembrolizumab for 2 years with complete response after 25 cycles and is currently without evidence of disease. She has been followed on surveillance, with no evidence of disease for more than 24 months following treatment.

Conclusion: This case represents the first to our knowledge to discuss re-treatment with pembrolizumab for relapsed choriocarcinoma after achieving a complete response.

1. Introduction

Gestational trophoblastic neoplasia (GTN) is a rare malignant transformation of placental trophoblastic cells that occurs weeks to years after any type of pregnancy. GTN encompasses invasive mole, placental-site trophoblastic tumor, epithelioid trophoblastic tumor, and gestational choriocarcinoma, the most aggressive histologic type characterized by early vascular invasion and widespread metastases. Programmed cell death ligand 1 signaling (PD1/PD-L1) likely plays an important role in the immunotolerance of normal pregnancy as well as in the development and persistence of GTN by protecting it from the maternal anti-tumor immune response. Current literature demonstrates diffuse PD-L1 expression in GTN, suggesting a role for anti-PD-1 blockade in chemotherapy-resistant tumors. To date, several case reports have demonstrated response with early treatment with checkpoint inhibitors (Huang et al., 2017; Clair et al., 2020; Panpal, 2021). While the use of immune checkpoint inhibitors (ICIs) has revolutionized the oncologic landscape, there is limited data evaluating efficacy of retreatment with ICIs (Yang, 2020). Furthermore, until recently, standard protocol guidelines regarding duration of treatment with checkpoint inhibitors were lacking, although evidence supports continuing for no more than 2 years (Weber, 2018). We present a case of recurrent metastatic choriocarcinoma re-treated with single agent pembrolizumab and review of available literature.

2. Case description

We present the case of a 44-year-old woman with a history of bilateral tubal ligation following a full-term delivery eight years prior, who visited her gynecologist for evaluation of a 1.5-year history of amenorrhea. Workup revealed an elevated human chorionic gonadotropin (hCG) of 2249 mIU/mL but no intrauterine pregnancy on ultrasound. The patient was subsequently managed with methotrexate for presumed ectopic pregnancy. However, hCG continued to rise to 2249 mIU/mL and CT imaging demonstrated a 9 × 9 × 12 cm left lower lobe lung mass and a 1.5 × 1 cm vascular lesion in the body of the pancreas.
(FIGO Stage IV, WHO Score 13). CT guided biopsy of the lung mass showed metastatic trophoblastic tumor. The patient was subsequently referred to our institution for further management.

She received EMA-CO for six cycles before hCG levels plateaued (Fig. 1). CT imaging showed resolution of the pancreatic mass and decrease in size of the lung mass with no new lesions. Regimen was then changed to EMA on day 1, 2 followed by etoposide and cisplatin on day 8 (EP) with normalization of hCG after three cycles and she received another 3 cycles past normalization.

3. Diagnostic assessment

The patient initially did well; however, one year following completion of her treatment, she presented to an outside hospital with hemoptysis due to recurrent disease. hCG at that time was 10 mIU/mL, and chemotherapy was re-started after pulmonary artery embolization. Chemotherapy with carboplatin and paclitaxel was started for two cycles, at which point hCG level had risen to 31 mIU/mL. A month later patient again presented to the hospital with hemoptysis at which point a PET CT revealed that the lung mass had decreased in size but was thicker and more metabolically active with two new enhancing masses in the left lower lobe, and hypermetabolic paratrachial and subcarinal lymph nodes. hCG was 26. She was subsequently referred back to our institution for further management.

Molecular profiling of the chest wall tumor from the original CT-guided biopsy in 2016 showed strong expression (90%) of PD-L1. Single agent pembrolizumab 200 mg IV every 21 days was started based on strong expression of PD-L1. Prior to starting pembrolizumab, her hCG was 26, but her hCG levels normalized to less than 5 mIU/mL after two cycles and another five cycles were given prior to discontinuation of treatment with complete response based on hCG levels. Six months later, hCG levels increased to 13.8 mIU/mL, and CT imaging revealed a persistent left lower lobe cavitary mass with areas of nodular enhancement consistent with recurrent disease.

4. Discussion

Standard of care for advanced stage or recurrent high risk choriocarcinoma involves multi-agent, chemotherapy with EMA-CO (Lurain et al., 2010) or EMA-EP given on day 1–2 and 8 continuously (Lurain and Nejad, 2005). For patients who progress on first or second-line combination chemotherapy, there are few alternatives for effective treatment and no standard treatment options. Molecular profiling suggests that strong PD-L1 expression in GTN may make checkpoint
Programmed cell death 1 is a transmembrane glycoprotein of the Ig superfamily that acts as a T-cell co-inhibitory receptor. Binding of PD-1 to its ligand (PD-L1 or programmed cell death ligand 2) results in inhibition of T cell activation and function, which ultimately down-regulates signaling from CD28 and T-cell co-receptor-CD3 complex (Sznol and Chen, 2013). In various solid tumors, upregulated expression of PD-L1 allows cancer to evade T-cell induced antitumor activity (Sznol and Chen, 2013). Pembrolizumab is a highly selective monoclonal IgG4 kappa isotype antibody against PD-1 which can disrupt PD-1 from its ligand (PD-L1 or programmed cell death ligand 2) results in inhibition of tumor malignancies (Jansen et al., 2019). Furthermore, in our experience with prior treatment, discontinuation after complete response did not result in recurrence. (Huang et al., 2017). While our patient tolerated treatment well, she was experiencing barriers to continuation of care (travel to appointments, time off work). Unfortunately, our patient did recur approximately six months after stopping pembrolizumab but based on known literature, decision was made to re-initiate therapy (Santini et al., 2018). Our patient completed 25 cycles after re-initiation of pembrolizumab, which she tolerated well with only mild myalgias, arthralgias and fatigue. In comparison, the standard regimens of EMA-CO and EMA-EP both have significant toxicity profiles in the short term (alopecia, fatigue, myelosuppression, nausea, and vomiting) and long term (myelodysplastic disease, leukemia, infertility). Pembrolizumab is generally well tolerated, administered once every three weeks, and has an acceptable tolerability profile, with immune-related adverse events that are generally manageable or reversible: pneumonitis, dermatologic and mucosal toxicity, colitis, hypeo/hyperthyroidism, and hematotoxicity (Naidoo et al., 2015). On the other hand, treatment with checkpoint inhibitors is associated with high treatment-related costs in the healthcare system, with an average of $9691 per cycle in the United States, and while many insurance plans cover the majority of the cost, medication necessity must be carefully weighed (Sarfatty et al., 2018).

Our case is the first to our knowledge to report complete response on re-treatment with pembrolizumab for relapsed choriocarcinoma after achieving a complete response with pembrolizumab. At the time of this manuscript, our patient with chemoresistant recurrent choriocarcinoma re-treated with pembrolizumab remains disease free (24 months). Other case reports have also suggested a promising role for pembrolizumab in the management of chemoresistant choriocarcinoma and GTN (Huang et al., 2017). Clinical trials utilizing checkpoint inhibitors for the management of choriocarcinoma are currently in progress. Future studies will need to include evaluation of duration of ICIs in GTN and correlate with outcomes.

5. Patient perspective

Investigators confirm that informed consent was obtained from the patient for creation and publication of this case report.

6. Statement of Consent

Investigators confirm that informed consent was obtained from the patient for creation and publication of this case report.
