Nitrogen isotopic signatures and fluxes of N₂O in response to land-use change on naturally occurring saline–alkaline soil

Arbindra Timilsina1,2,4*, Wenxu Dong1,4, Jiafa Luo1, Stuart Lindsey3, Yuying Wang1 & Chunsheng Hu1,2*

The conversion of natural grassland to semi-natural or artificial ecosystems is a large-scale land-use change (LUC) commonly occurring to saline–alkaline land. Conversion of natural to artificial ecosystems, with addition of anthropogenic nitrogen (N) fertilizer, influences N availability in the soil that may result in higher N₂O emission along with depletion of ¹⁵N, while converting from natural to semi-natural the influence may be small. So, this study assesses the impact of LUC on N₂O emission and ¹⁵N in N₂O emitted from naturally occurring saline–alkaline soil when changing from natural grassland (Phragmites australis) to semi-natural [Tamarix chinensis (Tamarix)] and to cropland (Gossypium spp.). The grassland and Tamarix ecosystems were not subject to any management practice, while the cropland received fertilizer and irrigation. Overall, median N₂O flux was significantly different among the ecosystems with the highest from the cropland (25.3 N₂O-N µg m⁻² h⁻¹), intermediate (8.2 N₂O-N µg m⁻² h⁻¹) from the Tamarix and the lowest (4.0 N₂O-N µg m⁻² h⁻¹) from the grassland ecosystem. The ¹⁵N isotopic signatures in N₂O emitted from the soil were also significantly affected by the LUC with more depleted from cropland (−25.3 ‰) and less depleted from grassland (−0.18 ‰). Our results suggested that the conversion of native saline–alkaline grassland with low N to Tamarix or cropland is likely to result in increased soil N₂O emission and also contributes significantly to the depletion of the ¹⁵N in atmospheric N₂O, and the contribution of anthropogenic N addition was found more significant than any other processes.

Nitrous oxide (N₂O) is a major long-lived anthropogenic greenhouse gas with about 265–298 fold greater potential for global warming in the atmosphere compared to carbon dioxide1. It is also an ozone-depleting substance2, produced mainly in the soil from nitrification and denitrification processes3. Its concentration in the atmosphere has increased to 331 ppb4 from 270 ppb in the pre-industrial age5. This increase of N₂O in the atmosphere is mainly attributable to rise in anthropogenic nitrogen (N) input to soil6,7 and this anthropogenic N input to soil increases as more natural ecosystems are converted to croplands.

Soil salinity can influence N₂O flux in different ways. An increase in salinity in a non-saline soil can increase8 or have no effect on N₂O emission9. Similarly, on naturally occurring saline soils, both decreases8 and increases10 in the N₂O flux have been found in response to increase in the salinity. These results suggest an ambiguous role of salinity in N₂O emission. Some meta-analyses11,12 have reported that alkaline soil emits less N₂O than neutral or acidic soil. In alkaline soil NH₄ may be converted to NH₃ and volatilize to the atmosphere whereas NH₄ is retained in acid soil, favoring N₂O formation13. N loss from alkaline soil may be high in total, but if much of the N is lost in the form of NH₃ there may be less NH₄ available for nitrification and subsequent denitrification. This evidence suggests that in naturally occurring saline–alkaline soil, the influence of both salinity and alkalinity may significantly affect the N₂O formation processes. So, quantifying N₂O flux from the saline–alkaline soil may help to increase knowledge on its contribution to soil-atmosphere exchange of N₂O.
Land-use change (LUC) from natural to semi-natural or artificial ecosystems can have different effects on N₂O emission. Specifically, conversion from natural to artificial ecosystems with the addition of N fertilizer significantly increases N₂O emission while conversion to semi-natural may or may not increase the emission. LUC directly impacts on soil physical, chemical and biological properties, the main factors affecting N₂O emission. N₂O emission from soil is reduced when pasture is forested, while conversion of rainforest to pasture or plantation leads to an increase in N₂O emission. A recent study found that the conversion of a conventional agricultural field to bio-energy crops had no effect on N₂O emission. Therefore, knowing which LUC practice is appropriate in terms of lower N₂O emissions, and its implementation could mitigate N₂O emission to the atmosphere and associated impact of climate change. Moreover, various LUC practices have different or no effect on N₂O emission, indicating that LUC is rather an indirect cause of N₂O emission. The main reason for the differences in N₂O emission due to LUC is probably the alteration of the controlling factors of N₂O production and reduction processes in the soil. So, quantifying N₂O flux from LUC, along with soil physical and chemical parameters, would further enable understanding of the main driving factors for N₂O production and consumption in the soil.

N has two stable isotopes i.e., ¹⁴N and ¹⁵N. &N in a sample is the deviation of the samples' ¹⁵N/¹⁴N from the respective isotope ratio of the reference material. Previously, the ¹⁵N in N₂O emitted from soil has been used to identify the processes for N₂O production i.e. nitrification and denitrification; however, using only ¹⁴N values in N₂O may mislead the interpretation as both the processes generally occur in the soils, possibly in different horizons or niche. The ¹⁵N in N₂O emitted from soil depends on the ¹⁵N content of the substrates i.e. NH₄ and NO₃, different microbial community composition, pH, temperature and substrate availability. Although it is difficult to predict the sources of N₂O emission using solely ¹⁴N signatures in the N₂O, these values could be used to distinguish between N₂O emitted from natural and artificial ecosystems. N addition in the artificial ecosystems increases the N in N₂O, while natural ecosystems to cropland may not influence the N₂O fluxes but also the ¹⁵N in the emitted N₂O as N availability is altered. For example, mean ¹⁵N in N₂O emitted from natural tropical forest, sub-tropical forest and subarctic soil are −18.0‰, −14.3‰, and −13.0‰, respectively; while more depleted after N application i.e., −37.9‰ to −34.3‰ in fertilized soil. The difference of ¹⁵N in N₂O is useful to distinguish N₂O emitted between fertilized and natural soils, and it arises from anthropogenic N addition to soil. Moreover, application of N fertilizer leads to high concentrations of NO in the soil, resulting in a decrease in N₂O reduction to N₂ and therefore a higher N₂O to N₂ ratio from the denitrification process. The reduction of N₂O to N₂ through denitrification leads to 1–24‰ ¹⁵N enrichment of the remaining N₂O. So, differences in the capacity to reduce N₂O to N₂ between various ecosystems may also influence the ¹⁵N in emitted N₂O.

To feed the world’s growing population requires an additional 2.7–4.9 Mha of cropland per year on average. Due to limited land resources, natural saline–alkaline areas are being reclaimed for producing food. Agricultural soil alone will contribute about 59% of total global N₂O emissions by 2030 as fertilizer application will need to increase by about 35–60% in the future. Therefore, it is important to quantify, and develop measures to mitigate increases in N₂O fluxes resulting from the conversion of natural saline–alkaline grassland to cropland. Furthermore, *Tamarix chinensis* (Tamarix), a salt-tolerant native species of shrub, is commonly used for the restoration of saline–alkaline soil in coastal areas in China (semi-natural ecosystem). Local governments have launched a coastal ecological restoration program promoting the planting of Tamarix; however, its effect on N₂O emission is unknown. Though Zhang et al. reported the differences in N₂O emission from various natural vegetation in saline–alkaline coastal areas, the impact of LUC from natural to semi-natural or artificial ecosystems on the dynamics of N₂O emissions from saline–alkaline soil is unknown. Moreover, different plant species have been reported to modify the soil characteristics in varying ways, resulting in significant changes in N₂O fluxes. Therefore, we hypothesize that: (1) LUC from native saline–alkaline ecosystem (grassland) to semi-natural (Tamarix) may significantly influence N₂O flux, along with soil environmental variables (soil temperature, soil moisture, ammonium, nitrate), because of the difference in plant species but have no effect on the ¹⁵N in N₂O emitted from the soil because there is no addition of anthropogenic N and (2) LUC from native saline–alkaline ecosystem (grassland) to artificial (cropland) may influence both N₂O flux and the ¹⁵N in N₂O due to anthropogenic N addition and changes in management practices. Therefore, we expect that the ¹⁵N in emitted N₂O could be used to distinguish N₂O emitted between unfertilized (natural and semi-natural ecosystems) and fertilized (cropland) ecosystems but not between different unfertilized ecosystems (grassland and Tamarix).

**Methods**

**Site description.** The study was carried out from April 2017 to June 2018 at the Haixing experimental station of the Center for Agricultural Resources Research (CARR), Institute of Genetics and Developmental Biology (IGDB), Chinese Academy of Sciences (CAS). This site is located near the Bohai sea in Haixing county (117°33′ E, 38°09′59″ N) of Hebei province, China (Fig. 1). The site has a semi-humid monsoon climate with more than 75% of precipitation occurring during the rainy season, i.e. from July to September. The mean annual precipitation is 582 mm. The groundwater table is at 0.9–1.5 m depth. The soil in this area is classified as solonchak (18.1% clay and 7.8% sand). The salt content in the area ranges from 3 to 20 g kg⁻¹ soil. In 2008, the native grassland was converted to Tamarix and cropland with the aim of reclamation of the saline–alkaline soil. The Tamarix stand was left to grow naturally after plantation. For this reason, we consider it as a semi-natural ecosystem. The cropland (artificial ecosystem) has permanent plots 7.25 m × 7.25 m in size, which were left fallow after conversion until 2014. During the fallow period, the cropland plots were irrigated (180 mm per year) around early January with saline groundwater. The irrigated water freezes from January to late February or early March as air temperatures are mostly below 0 °C. The salinity of the irrigated groundwater was 7–27 g l⁻¹. This practice of irrigation reduces the salinity in the soil and decrease the salt stress on subsequently
planted cotton seedlings. Since 2014, during each March, the cropland has been covered with plastic film until the sowing of the cotton to reduce the evapotranspiration. The cropland received 400 kg N ha$^{-1}$ year$^{-1}$ applied during May every year (200 kg N ha$^{-1}$ organic fertilizer + 200 kg N ha$^{-1}$ diammonium phosphate) before sowing cotton since 2014. During this experimental period, cropland was fertilized on 7th May 2017 and 6th May 2018 and irrigation occurred on 10th Jan 2018. The irrigated water had melted completely by 21st Feb 2018. Other details of the three ecosystems are reported in Table 1.

Gas sampling. In each ecosystem, four closed static chambers were randomly placed. The chambers were made of polyvinyl chloride (PVC) and measured $60 \times 20 \times 40$ cm ($L \times B \times H$) and each chamber contained a fan to homogenize the air. The chambers were fitted with a thermometer and a sampling tube with a three-way stopcock. Both sampling tube and thermometer were sealed where they passed through the surface of the chamber to prevent leakage. Five 40-ml gas samples were taken for N$_2$O concentration analysis at 20 min intervals using a glass syringe, while two 160-ml gas samples were taken at 0 and 80 min and stored in glass bottles for $\delta^{15}$N-N$_2$O analysis. Gas was sampled between 8:00 AM to 12:00 PM. Sampling was done twice to thrice in a month during March to September (warm season) while once in a month during October to February (cold season).
Table 1. Management practices, dominant vegetation and some physical and chemical soil parameters of the three ecosystems. Different letters in the row indicate significant differences (<0.05), while no letters means no difference.

| S. no | Ecosystem | Management practice | Dominant plant species | Soil bulk density (g cm⁻³) | Soil pH | Soil salinity (mS cm⁻¹) |
|-------|-----------|---------------------|------------------------|-----------------------------|--------|-------------------------|
| 1     | Grassland | Native grassland, no grazing, no cutting, no fertilizer | Common reed (*Phragmites australis*) | 1.56 ± 0.04a | 8.74 ± 0.07 | 2.29 ± 0.19 |
| 2     | Cropland  | Converted from the grassland, fertilizer use (organic + chemical), irrigation once a year | Cotton (*Gossypium* spp., *Lumian 28*) | 1.58 ± 0.01a | 8.45 ± 0.06 | 2.17 ± 0.29 |
| 3     | Tamarix   | Converted from the grassland, no fertilizer use, no cutting, no litter removal | *Tamarix* (*Tamarix chinensis*) | 1.38 ± 0.02b | 8.58 ± 0.04 | 2.15 ± 0.10 |

\[ \delta \text{N}_{\text{soil-emitted} \text{N}_2\text{O}} = (\delta \text{N}_{\text{measured}} \times \text{C}_{\text{N}_2\text{O}_{\text{measured}}} - \delta \text{N}_{\text{atmosphere}} \times \text{C}_{\text{N}_2\text{O}_{\text{atmosphere}}}) / (\text{C}_{\text{N}_2\text{O}_{\text{measured}}} - \text{C}_{\text{N}_2\text{O}_{\text{atmosphere}}}) \] (2)

where $\delta \text{N}_{\text{measured}}$ and $\text{C}_{\text{N}_2\text{O}_{\text{measured}}}$ are the $\delta \text{N}$ and concentration of the $\text{N}_2\text{O}$ sample at time 80 min after the closure of the chamber, while the $\delta \text{N}_{\text{atmosphere}}$ and $\text{C}_{\text{N}_2\text{O}_{\text{atmosphere}}}$ are the $\delta \text{N}$ and concentration of the sample at time zero (immediately after the closure of the chamber). When the fluxes were lower than 10 $\mu$g m⁻² h⁻¹, the $\text{N}_2\text{O}$ fluxes were excluded from the results due to errors introduced with lower fluxes.

**Measurement of soil parameters.** Soil temperature at 5 cm depth was taken using a thermometer inserted into the soil. Each day after the gas sample collection, soil samples (0–20 cm) were collected from the area nearby the chambers. Thermo-gravimetric technique (oven-drying) method was used to measure the soil moisture content. Water filled pore space (WFPS) was calculated using a formula as stated in Eq. (3):

\[ \text{WFPS (％)} = (\text{SWC} \times \text{BD}) / (\text{BD} / \text{PD}) \times 100\% \] (3)

where SWC is soil water content (g g⁻¹), BD is bulk density (Mg m⁻³), and PD is particle density (2.65 Mg m⁻³).

For soil pH and electrical conductivity (Ec), 10 g of air dried (< 2 mm) soil sample was weighed and mixed with 25 and 50 ml of deionized water, respectively. Then the mixture was mechanically shaken for 1 h. pH was determined in a suspension with a pH meter (METTLER TOLEDO FE20) at 1:2.5 soil–water ratio. Ec was measured using an Ec meter (METTLER TOLEDO SG7) with 1:5 soil–water ratio at room temperature. Soil ammonium (NH₄-N) and nitrate (NO₃-N) concentrations were measured using the KCl extraction method. For this, 10 g of fresh soil was mixed with 50 ml of freshly prepared 1 M KCl and the mixture was shaken for one hour, then it was filtered through Whatman 42 filter paper. Then, NH₄-N and NO₃-N concentrations of the filtrate were measured by using a Smartchem140 and a UV spectrophotometer, respectively.

\[ \text{WFPS (％)} = (\text{SWC} \times \text{BD}) / (\text{BD} / \text{PD}) \times 100\% \] (3)

where SWC is soil water content (g g⁻¹), BD is bulk density (Mg m⁻³), and PD is particle density (2.65 Mg m⁻³).

For soil pH and electrical conductivity (Ec), 10 g of air dried (< 2 mm) soil sample was weighed and mixed with 25 and 50 ml of deionized water, respectively. Then the mixture was mechanically shaken for 1 h. pH was determined in a suspension with a pH meter (METTLER TOLEDO FE20) at 1:2.5 soil–water ratio. Ec was measured using an Ec meter (METTLER TOLEDO SG7) with 1:5 soil–water ratio at room temperature. Soil ammonium (NH₄-N) and nitrate (NO₃-N) concentrations were measured using the KCl extraction method. For this, 10 g of fresh soil was mixed with 50 ml of freshly prepared 1 M KCl and the mixture was shaken for one hour, then it was filtered through Whatman 42 filter paper. Then, NH₄-N and NO₃-N concentrations of the filtrate were measured by using a Smartchem140 and a UV spectrophotometer, respectively.

Statistics. Data were not normally distributed for all variables. Several possible transformations were tried without success. As our main objectives were to examine differences in \( \text{N}_2\text{O} \) fluxes and \( ^{15}\text{N} \) in soil emitted \( \text{N}_2\text{O} \) in different ecosystems, we conducted the Kruskal Wallis ANOVA (analysis of variance) followed by the Mann Whitney test. The same analysis was used for other measured soil parameters. Similarly, differences in annual cumulative flux between ecosystems were computed through the Kruskal Wallis ANOVA followed by the Mann Whitney test. Spearman correlation analysis was applied to examine the relationships among the measured variables and \( \text{N}_2\text{O} \) flux. When \( p \) values were less than 0.05 the differences was considered significant. All the figures and statistical analyses were computed in Origin Pro 8 (Origin Lab Ltd., Guangzhou, China).

Results
Soil environmental variables. The pattern of soil temperature was consistent with the air temperature (Fig. 2a,b). Soil temperature at 5 cm soil depth showed a clear and similar seasonal variation (high in summer and low in winter) in all ecosystems. The lowest temperature was – 4 ℃ reported in January while the highest temperature was 42 ℃ in July. Soil temperature at 5 cm depth at grassland was similar to the cropland and Tamarix. While the Tamarix had significantly \((p < 0.05)\) lower soil temperatures than the cropland. The median soil temperature was 24.5 ℃, 25.3 ℃ and 23.5 ℃ in the grassland, cropland and Tamarix, respectively.

The overall WFPS of the Tamarix was significantly \((p < 0.001)\) than the grassland and cropland. The median value of WFPS in the grassland was 89.6% (ranging from 66.9 to 99.95%), cropland was 90.4% (ranging from 73.32 to 99.97%) and Tamarix was 76.2% (ranging from 44.4 to 97.0%). As water table was around 0.9–1.5 m, normally WFPS exceeded 70% in all ecosystems (Fig. 3a).

Soil \( \text{NH}_4 \) was significantly \((p < 0.01)\) higher in the grassland compared to the cropland and Tamarix. Overall, median \( \text{NH}_4 \) concentration in the grassland was 0.55 mg kg\(^{-1}\) (ranging from 0.006 to 4.0 mg kg\(^{-1}\)), 0.35 mg kg\(^{-1}\) (ranging 0.006–6.4 mg kg\(^{-1}\)) in the cropland and 0.31 mg kg\(^{-1}\) (ranging from 0.01 to 1.2 mg kg\(^{-1}\)) in the Tamarix.
Grassland and cropland showed higher temporal variation in soil NH$_4$ than the Tamarix during the sampling period (Fig. 3b). After fertilization of the cropland, there was a peak in NH$_4$ content.

Soil NO$_3$ was significantly different (p < 0.001) among all three ecosystems. The order of soil NO$_3$ was: cropland > Tamarix > grassland. The median concentration of NO$_3$ in the grassland was 1.0 mg kg$^{-1}$ (ranging 0.004–14.0 mg kg$^{-1}$), 65 mg kg$^{-1}$ (6.4–209 mg kg$^{-1}$) in the cropland and 12.3 mg kg$^{-1}$ (ranging from 2.6 to

Figure 3. Soil water-filled pore space (WFPS) (a), Soil NH$_4$ (b), and NO$_3$ (c) of the top 20 cm soil. The arrows represent fertilizer application event. Each point represents a thematic mean of n = 1–4 ± SE.
34.30 mg kg\(^{-1}\)) in the Tamarix. For some sampling dates, NO\(_3\) was below the limit of detection in the grassland soil. Fertilizer application in the cropland led to a peak in NO\(_3\) content in the soil (Fig. 3c).

**N\(_2\)O fluxes and annual cumulative emission.** Among the 24 sampling occasions, 9 occasions were found negative fluxes in the grassland, but in the cropland and Tamarix there were always positive fluxes (Fig. 4). Overall, N\(_2\)O fluxes were significantly different (p < 0.001) among the ecosystems. The median N\(_2\)O flux was 4.0 N\(_2\)O-N µg m\(^{-2}\) h\(^{-1}\) (ranging from −22.0 to 1.1 for negative flux and 2.8 to 117.7 4 N\(_2\)O-N µg m\(^{-2}\) h\(^{-1}\) for the positive flux, over the study period), 25.3 N\(_2\)O-N µg m\(^{-2}\) h\(^{-1}\) (ranging from 2.0 to 678.04 N\(_2\)O-N µg m\(^{-2}\) h\(^{-1}\)) and 8.2 N\(_2\)O-N µg m\(^{-2}\) h\(^{-1}\) (ranging from 0.5 to 179.0 N\(_2\)O-N µg m\(^{-2}\) h\(^{-1}\)) from the grassland, cropland and Tamarix, respectively. The peak fluxes in the cropland occurred after the application of fertilizer (Fig. 4). In 2017, after fertilization the N\(_2\)O peak lasted for two weeks. While in 2018, on the day of fertilization there was a small increase, then the highest peak occurred in the 4th week after fertilization. Results for February 2018 and the 3rd week after fertilization in 2018 are not reported because it was noted that there were unusually high concentrations of N\(_2\)O (4 times higher than usual atmospheric concentration) in all samples taken at time zero, which may have led to errors in interpretation of results. For two of the sampling points, high N\(_2\)O emissions from Tamarix were observed. This occurred during the decomposition of a large number of pill-bugs that had died at the site (the reason for the pill-bug deaths is unknown).

The annual cumulative N\(_2\)O emissions were significantly different (p < 0.05) among all three ecosystems. The annual cumulative N\(_2\)O emissions increased in the order of cropland > Tamarix > grassland. Cropland emitted 3.5 kg N\(_2\)O-N ha\(^{-1}\) year\(^{-1}\) (ranging from 2.7 to 3.9 kg N\(_2\)O-N ha\(^{-1}\) year\(^{-1}\)) about 1.7 times more than the Tamarix,
which emitted 1.3 kg N\textsubscript{2}O-N ha\(^{-1}\) year\(^{-1}\) (ranging from 0.9 to 1.6 kg N\textsubscript{2}O-N ha\(^{-1}\) year\(^{-1}\)), and 7 times more than the grassland (0.5 kg N\textsubscript{2}O-N ha\(^{-1}\) year\(^{-1}\), ranging from 0.3 to 0.7 kg N\textsubscript{2}O-N ha\(^{-1}\) year\(^{-1}\)) (Fig. 5).

Relationship between soil environmental variables and N\textsubscript{2}O flux. Spearman correlation analysis showed various relationships between N\textsubscript{2}O flux and soil environmental variables measured at three studied ecosystems (Table 2). In grassland, there was no significant relationship between N\textsubscript{2}O flux and any of the measured soil parameters. In the cropland, the analysis showed significant positive correlations of N\textsubscript{2}O flux with soil temperature, NH\(_4\) content, and NO\(_3\) content. There was no significant correlation between N\textsubscript{2}O emission and WFPS in the cropland. Analysis of the Tamarix results showed that there were significant positive correlations of N\textsubscript{2}O flux with soil temperature and NO\(_3\) content, while there was a negative relationship with WFPS.

15N isotopic signature of soil-emitted N\textsubscript{2}O. There was a significant difference (p < 0.01) in the 15N isotopic signature of soil-emitted N\textsubscript{2}O between the three ecosystems (Fig. 6). The difference between grassland and Tamarix was at the level of p < 0.01 while between grassland and cropland was at the level of p < 0.001, suggesting N addition has strong effect on depletion of 15N in N\textsubscript{2}O. N\textsubscript{2}O emitted from cropland was more depleted in 15N while N\textsubscript{2}O emitted from grassland was less depleted. The median 15N values in emitted N\textsubscript{2}O were −0.18 ‰ (ranging from −41.0 to 5.8 ‰, n = 14), −25.3 ‰ (ranging from −68.3 to 4.6 ‰, n = 63) and −13.7 ‰ (ranging from −50.5 to 3.0 ‰, n = 32) for the grassland, cropland and Tamarix, respectively. Due to problems with the IRMS, results from the beginning of the experiment are not included. In the grassland, due to low and negative fluxes of N\textsubscript{2}O, it was not always possible to calculate 15N values in soil-emitted N\textsubscript{2}O. Emitted N\textsubscript{2}O was more depleted in 15N in April in the grassland while in the Tamarix it was during the pill-bug decomposition period. In the cropland, it was just after the application of N fertilizer and this continued for about three weeks after the fertilization, then in the fourth week, when N\textsubscript{2}O emission reached its highest peak, the values returned to the normal range (Figs. 5, 6). There was no significant relationship between measured parameters and 15N in soil-emitted N\textsubscript{2}O.

Discussion
At our experimental site, we had a unique opportunity to investigate the impact of land-use change (LUC) from natural to semi-natural and artificial ecosystems on N\textsubscript{2}O flux and its 15N within the same climatic conditions and soil type. LUC is associated with changes in various land cover types as a result of different management

Table 2. Spearman correlation analysis between soil environmental variables and N\textsubscript{2}O flux in different ecosystems. "*" represents significant relationship (p < 0.05).
practices, which then can lead to changes in soil physical, chemical and biological properties. The changes in these soil properties can alter soil greenhouse gas emissions. Soil humidity, temperature, NH₃ content and NO₃ content are the major soil parameters that influence N₂O emission from soil. With the change in the land use, it was observed that these soil parameters were significantly influenced at our study site, which may have led to the differences in N₂O flux from the different ecosystems.

In the grassland, no studied soil parameters were significantly correlated to N₂O flux, which may have been due to limited NO₃ content. The relatively high NH₃ content and low NO₃ in grassland soils indicate inhibition of nitrification process, causing low N₂O emissions. The positive correlation between soil temperature and N₂O emission in the cropland and Tamarix, observed in our study is consistent with other studies and can be explained by the increase in microbial activity with an increase in temperature. WFPS higher than 80% is favorable for N₂O reduction to N₂. Low N content along with higher WFPS and frequent N₂O uptake results in the grassland site indicate that denitrification is a dominant process of N₂O emission. Optimum WFPS for N₂O emissions ranges from 60 to 80% and there have been reports of significant positive to negative or no relationship between WFPS and N₂O emission. Increase in soil moisture has a greater effect when dry soil is wetted. So, higher WFPS (around 90%) in grassland and cropland might not be limiting factor controlling N₂O emissions in our study. We only observed significant relationship between WFPS and N₂O flux in Tamarix. The negative relationship might be due to excessive WFPS than that is required for optimum N₂O production. NH₃ and NO₃ are the main substrates for nitrification and denitrification. Significant positive relationships between N₂O emission and both NH₃ and NO₃ have previously been demonstrated indicating that coupled nitrification–denitrification contributes to N₂O formation in the soil. Similarly, in the current study positive relationships were found between N₂O flux and NH₃ and NO₃ content in the cropland; however, only with NO₃ in the Tamarix. It can be difficult to identify the N₂O formation process responsible or the emissions i.e. either nitrification or denitrification, as both processes can occur simultaneously in the soil. The results showing a range of both positive and negative relationships between various soil environmental parameters and N₂O flux indicate that N₂O formation processes have complex interactions with these soil parameters.

Often ecosystems with low N content have a negative flux and low annual N₂O emission. The grassland site in our study was like most natural ecosystems, N limited with low atmospheric nitrogen input and densely rooted vegetation and therefore emitted less N₂O. High WFPS with low N content favors denitrification leading to N₂O consumption. However, relatively dry ecosystems have also been reported to consume atmospheric N₂O, however, the possible mechanisms of N₂O consumption by soil under dry conditions are not well understood. N₂O uptake has been observed at low NO₃ levels (~1 mg N kg⁻¹) and NH₄ content (<2 mg N kg⁻¹) levels and high WFPS (90%) indicating that coupled nitrification–denitrification contributes to N₂O formation in the soil. The grassland conditions in the current study were similar to these previous findings that may be the reason for N₂O uptake occurring in the grassland in some sampling occasions. It has also been observed that soil under different plant species can have different rates of N₂O reduction and that N₂O consumption rate decreases with increase in soil NO₃. In the cropland and Tamarix systems in the present study, NO₃ content was significantly higher than in the grassland, which might have resulted in a decrease in the reduction of N₂O to N₂, leading to the higher emission of N₂O. The more depleted ¹⁵N values in soil-emitted N₂O in the cropland and Tamarix compared to the grassland (Fig. 6) is further evidence of a decrease in the reduction of N₂O to N₂ in those systems.

Overall, N₂O flux in the grassland was low (4.0 N₂O-N µg m⁻² h⁻¹) with an annual cumulative emission of 0.5 kg N₂O-N ha⁻¹ year⁻¹. These findings are similar to those observed in other studies on natural grassland under different climatic conditions on non-saline soils. However, compared to a saline grassland with the same dominant vegetation, the flux rate in the current study was low. This was possibly due to the low NO₃ and NH₄ content. When natural grasslands with low N content are converted to cropland, the addition of a large amount of N fertilizer may potentially contribute to high N₂O emissions. Consistent with this, the cropland in the current study emitted about 7 times more N₂O than the grassland. The annual N₂O emission rate was similar to the IPCC default emission factor, i.e. 1% of applied N fertilizer is emitted as N₂O in the agricultural fields. The observed N₂O emission from our cropland was lower than that from non-saline–alkaline soils in the same climatic area under application of the same amount of fertilizer. Similarly, the N₂O flux from some non-saline–alkaline soils, receiving a similar rate of fertilizer, was three times higher than from the cropland in our study. A saline–alkaline sunflower field, receiving 300 kg N ha⁻¹ year⁻¹, emitted 9.8 kg N ha⁻¹ year⁻¹, which is 3.8 times higher than the emission rate from the cropland in the current study, which had 400 kg N ha⁻¹ year⁻¹ applied. The Tamarix ecosystem emitted 2.6 times more N₂O than the native grassland. This increase can be attributed to the higher NO₃ content. The increase in NO₃ content could also be linked to a lower reduction of N₂O to N₂ in the Tamarix system because high NO₃ inhibits N₂O reduction. Conversion of grassland to tree plantations has a contrasting (increased to no influence) effect on N₂O emission. Overall, our results support our hypothesis that conversion of native grassland to cropland or Tamarix ecosystems would lead to changes in soil environmental variables and an increase in N₂O emission.

When compared with studies involving similar land use change (Supplement Information S1) our results from the respective ecosystems are within the ranges reported in the literature. This result suggests that saline–alkaline soils may not always have a higher potential for N₂O emission, as hypothesized by Ghosh et al. and Yang et al. For the cropland the fertilizer application rate was higher than other studies in the literature (Supplement Information S1), this is likely to have led to the higher rate of N₂O emission from the cropland. In saline–alkaline soil, NH₃ can be converted to NH₄ and lost to the atmosphere, which may decrease the probability of N₂O formation due to nitrification. Two meta-analyses reported that alkaline soils emit less N₂O compared to natural and acidic soils. Furthermore, high salinity inhibits both nitrification and denitrification processes. These negative effects of both salinity and alkalinity on N₂O production processes and emissions further suggest that saline–alkaline soil may not emit more N₂O.
It is evident from previous research\(^{25,28}\) that there may be differences in the \(^{15}\)N in soil-emitted \(\text{N}_2\text{O}\) between fertilized and unfertilized ecosystems. Therefore, significant differences were expected in the \(^{15}\)N isotopic signatures in soil-emitted \(\text{N}_2\text{O}\) between the unfertilized ecosystems (grassland and Tamarix) and the fertilized cropland. As there was no anthropogenic N input in grassland and Tamarix, our expectation was \(^{15}\)N in \(\text{N}_2\text{O}\) would be similar in these two ecosystems. However, differences were observed among all three ecosystems. The \(^{15}\)N in \(\text{N}_2\text{O}\) emitted from the grassland, cropland, and Tamarix were all within the range reported by other studies\(^{25,26,28,29,71}\). As we can see from Fig. 6 that temporal variability of \(^{15}\)N in soil-emitted \(\text{N}_2\text{O}\) was highest in cropland, indicating that N cycling process in the cropland is relatively open. The more depleted \(^{15}\)N in \(\text{N}_2\text{O}\) emitted from the cropland implies that N availability can be considered enhanced (due to the high rate of N fertilizer) in the ecosystem\(^{25}\). When nitrogen availability is enhanced, the \(\text{N}_2\text{O}\) production process favors larger \(^{15}\)N fractionation, leading to more depleted \(^{15}\)N in \(\text{N}_2\text{O}\) from the soil\(^{25,72}\). This phenomenon can lead to differences in the \(^{15}\)N in \(\text{N}_2\text{O}\) emitted from the grassland and Tamarix, as observed in this study. After application of fertilizer the cropland could be considered to have unlimited N availability so the \(\text{N}_2\text{O}\) emitted was strongly depleted in \(^{15}\)N, indicating the production of \(\text{N}_2\text{O}\), either by nitrification or denitrification, favored larger \(^{15}\)N fractionation rather than shift from denitrification to nitrification\(^{25,26,28,71}\). Although \(^{15}\)N values in soil-emitted \(\text{N}_2\text{O}\) can sometimes be used to predict sources of \(\text{N}_2\text{O}\) when combined measurements of \(^{15}\)N values in substrates for \(\text{N}_2\text{O}\) production\(^{25,26}\) and molecular analysis of \(\text{N}_2\text{O}\) producing organisms\(^40\), with data from this trial was not possible to estimate relative contributions of nitrification and denitrification. Moreover, more powerful tools like \(^{15}\)N site preference (SP) is a good indicator of production pathways\(^{24,73,74}\), which was not used in this study, making difficult to generalize dominant process of \(\text{N}_2\text{O}\) production in different ecosystems.

Contrarily to our hypothesis, there was a difference between \(^{15}\)N in soil-emitted \(\text{N}_2\text{O}\) within unfertilized (grassland and tamarix) ecosystems. The reason for differences in the \(^{15}\)N in \(\text{N}_2\text{O}\) between the grassland and Tamarix may be a difference in \(\text{N}_2\text{O}\) reduction capability. It is likely that \(\text{N}_2\text{O}\) reduction in the grassland (as evidenced by \(\text{N}_2\text{O}\) consumption) enriched the \(^{15}\)N in \(\text{N}_2\text{O}\), so when it was emitted to the atmosphere it was less depleted than \(\text{N}_2\text{O}\) emitted from soil in which reduction has not occurred\(^{29,75}\). A possible reason for the reduction of \(\text{N}_2\text{O}\) being favored in the grassland soil may be the low concentrations of \(\text{NO}_3\)\(^69\) and high WFPS\(^22\). For this reason reduction of \(\text{NO}_3\) to \(\text{N}_2\) might be more prominent in the grassland compared to the Tamarix. However, it could be a possibility that gross \(\text{N}_2\text{O}\) consumption may be masked by higher rates of \(\text{N}_2\text{O}\) production\(^{76}\) in the cropland and Tamarix. The \(^{15}\)N isotope content of the substrates (\(\text{NH}_4\) and \(\text{NO}_3\)) for \(\text{N}_2\text{O}\) production were not measured in the current study, which could have provided more insight into the reason for the observed differences between the ecosystems. The \(^{15}\)N differences in the emitted \(\text{N}_2\text{O}\) between ecosystems could also be due to variation in the microbial community composition in the soils\(^77\). Several factors favor complete denitrification, such as differences in microbial community composition (denitrifiers), presence of denitrification enzymes, high soil water content, high soil pH, a low rate of \(\text{O}_2\) diffusion and presence of labile carbon\(^\text{15}\). So differences in those factors should not be ruled out as causes for the differences in the \(^{15}\)N content in emitted \(\text{N}_2\text{O}\) between the ecosystems.

The \(^{15}\)N content in atmospheric \(\text{N}_2\text{O}\) has been decreasing since the preindustrial age\(^{28}\); however, atmospheric \(\text{N}_2\text{O}\) concentration is increasing\(^7\). This decrease in the \(^{15}\)N in \(\text{N}_2\text{O}\) has been considered as a result of an increase in the use of chemical fertilizer\(^{25,28}\). Moreover, global decline in the \(\text{N}_2\text{O}\) reduction process relative to production might also contribute to the decrease in the \(^{15}\)N\(^28\). Our results indicate that the conversion of natural ecosystems to cropland with the addition of anthropogenic N would greatly contribute to the depletion of the \(^{15}\)N in atmospheric \(\text{N}_2\text{O}\) by emitting more depleted \(^{15}\)N in \(\text{N}_2\text{O}\) along with higher \(\text{N}_2\text{O}\) emission rate, which was according to our hypothesis. Moreover, if ecosystems with more reduction capability (such as grassland) are converted to Tamarix that have less reduction capability (assumed due to the absence of measured atmospheric \(\text{N}_2\text{O}\) consumption in our study), this would also play a role in the depletion of \(^{15}\)N in atmospheric \(\text{N}_2\text{O}\). Overall, it can be concluded that the addition of anthropogenic N to cropland would contribute more to deplete \(^{15}\)N in atmospheric \(\text{N}_2\text{O}\) than any other processes.

Conclusions

Our study showed that LUC from native grassland to Tamarix and cropland on saline–alkaline soil significantly influence soil temperature, soil moisture and \(\text{NH}_4\) and \(\text{NO}_3\) contents. The changes in these soil factors, along with the observed correlations between \(\text{N}_2\text{O}\) fluxes and the soil parameters, could explain the differences in \(\text{N}_2\text{O}\) flux caused by the LUC. Saline–alkaline soil may not always act as a potentially high source of \(\text{N}_2\text{O}\), as our fluxes and annual emissions result are in the usual ranges for the respective ecosystems reported in the literature. The conversion from native grassland to Tamarix ecosystem increased more \(\text{N}_2\text{O}\) 2.6 times while cropland increased 7 times. The LUC also influenced the \(^{15}\)N in soil-emitted \(\text{N}_2\text{O}\), greatly depleting it in cropland and moderate in Tamarix compared to native grassland. The differences in the \(^{15}\)N in soil-emitted \(\text{N}_2\text{O}\) between the fertilized and unfertilized ecosystems could be attributable to anthropogenic N fertilization. The differences in the \(^{15}\)N in \(\text{N}_2\text{O}\) between the unfertilized ecosystems (grassland and Tamarix) could be attributable to the \(\text{N}_2\text{O}\) reduction capacity of native grassland. Our results further suggest that the depletion of the \(^{15}\)N in atmospheric \(\text{N}_2\text{O}\) since the pre-industrial age could be highly attributable to anthropogenic N addition and to lesser extent to land-use changes where ecosystems with more \(\text{N}_2\text{O}\) reduction capacity have been converted to ecosystems with less \(\text{N}_2\text{O}\) reduction capacity.

Acknowledgements
This work was funded by the National Natural Science Foundation of China (no. 41530859) the National Key Research and Development Program of China (2016YFD0800102-4 and 2018YFC0213300-01). Arbindra Timilsina is grateful to CAS-TWAS President’s Fellowship Programme for granting the fellowship. We are also thankful to Mr. Gokul Gaudel and Dr. Bikram Pandey for helping to draw the map of the study site.

Author contributions
A.T., C.H., Y.W., and W.D. designed the experiment. A.T. performed all the field and laboratory work. A.T. analyzed the data and wrote the manuscript. C.H., Y.W., and W.D. interpreted the data. J.L. and S.L. gave critical comments to improve the manuscript.

Competing interests
The authors declare no competing interests.
