ABSTRACT

We report three-minute oscillations in the solar chromosphere driven by a strong downflow event in a sunspot. We used the Fast Imaging Solar Spectrograph of the 1.6 m New Solar Telescope and the Interface Region Imaging Spectrograph (IRIS). The strong downflow event is identified in the chromospheric and transition region lines above the sunspot umbra. After the event, oscillations occur at the same region. The amplitude of the Doppler velocity oscillations is $2\,\text{km}\,\text{s}^{-1}$ and gradually decreases with time. In addition, the period of the oscillations gradually increases from 2.7 to 3.3 minutes. In the IRIS 1330 Å slit-jaw images, we identify a transient brightening near the footpoint of the downflow detected in the H$_\alpha$+$0.5$ Å image. The characteristics of the downflowing material are consistent with those of sunspot plumes. Based on our findings, we suggest that the gravitationally stratified atmosphere came to oscillate with a three-minute period in response to the impulsive downflow event as was theoretically investigated by Chae & Goode.

Key words: Sun: atmosphere – Sun: chromosphere – Sun: oscillations

1. INTRODUCTION

Ever since discovery of three-minute umbral oscillations (Beckers & Tallant 1969; Beckers & Schultz 1972; Giovanelli 1972), they have been studied for several decades by numerous authors (for reviews, see Staude 1999; Bogdan & Judge 2006; Khomenko & Collados 2015). The oscillations are detected in the multiple layers of the solar atmosphere above sunspot umbrae (e.g., Lites & Thomas 1985; Thomas et al. 1987; Maltby et al. 1999; O’Shea et al. 2002). They are generally manifested as periodic fluctuations of intensity and velocity. The oscillations are commonly regarded as slow magnetoacoustic waves upwardly propagating in the gravitationally stratified medium, as the oscillations in the higher atmosphere lag behind those in the lower atmosphere (Brynjildsen et al. 1999, 2004; Tian et al. 2014). It is believed that the power of the three-minute oscillations may mostly come from the photosphere or below it. Two specific processes are currently considered as the major candidates for the driver of the oscillations: $p$-mode absorption of global solar oscillations and magnetoconvection inside sunspots (see the review by Khomenko & Collados 2015 and references therein).

Theory predicts that the three-minute umbral oscillations can be excited by impulsive disturbances inside the atmosphere as well. Early studies by Lamb (1909) and Kalkofen et al. (1994) showed that the atmosphere disturbed by an impulsive disturbance at a point begins to oscillate with frequency asymptotically approaching the acoustic cutoff frequency. The recent study of Chae & Goode (2015) found that the necessary condition for the cutoff frequency oscillations to have enough power is the occurrence of the impulsive disturbance of large vertical extent. Since there are many activities in the chromosphere, we expect that impulsive disturbances that produce the three-minute oscillations occur even though they may not be the major driver of such oscillations. Despite this expectation, so far there has been no observational report of such three-minute oscillations generated by impulsive events in the chromosphere above sunspots. This is in contrast with the common findings of oscillations and waves in the corona driven by the strongest impulsive events such as flares (Aschwanden et al. 1999; Nakariakov et al. 1999; Schrijver et al. 2002), lower coronal eruptions/ejections (Zimovets & Nakariakov 2015), and filament destabilizations (Schrijver et al. 2002). Strong X-class flares even affect the solar interior and cause sunquakes which are acoustic waves produced in the photosphere (Kosovichev & Zharkova 1998; Kosovichev 2006). Probably, the impulsive events leading to three-minute oscillations in the chromosphere may be too small and too weak to be detected.

In this Letter, for the first time we report on the occurrence of the three-minute oscillations driven by an impulsive disturbance in the chromosphere. In this specific study, the disturbance was caused by a strong downflow event detected in the chromospheric and transition region (TR) lines above a sunspot umbra. It is important to understand the properties of the oscillations and waves in order to estimate physical quantities of the medium for further study. We analyze multi-wavelength data acquired by the Fast Imaging Solar Spectrograph (FISS; Chae et al. 2013) installed at the 1.6 m New Solar Telescope (NST) of Big Bear Solar Observatory and Interface Region Imaging Spectrograph (IRIS; De Pontieu et al. 2014).

2. OBSERVATIONS AND DATA ANALYSIS

We observed a small sunspot in NOAA active region 12172 on 2014 September 27. It was located between a leading main sunspot and a trailing main sunspot. The region of our interest was so variable that the morphology of the small sunspot kept changing within several hours, and the sunspot finally disappeared the day after our observation period. The FISS is a dual-band Échelle spectrograph that records the H$_\alpha$ band and the Ca ii 8542 Å band simultaneously with imaging capability. Imaging is done by fast scanning of a slit over the field of view (FOV), and the step size is 0.616. With this instrument, we acquired data for an hour from 17:03:40 to 18:00:50 UT with...
the aid of the adaptive optics system. The spatial sampling along the slit is 0.16", and the spectral samplings are 0.019 Å and 0.026 Å at the Hα line and the CaII line, respectively. The FOV of the raster image is 24" × 40", and the time cadence is 22 s.

The IRIS observation was done with large coarse two-step raster mode from 11:29:36 to 17:36:50 UT, and we analyzed the data taken from 17:03:45 to 17:36:29 UT that correspond to the overlapping period with the FISS data. The IRIS spectra were acquired in the near-ultraviolet (NUV; 2783–2834 Å) and far-ultraviolet (FUV; 1332–1358 Å, 1390–1406 Å) band, and we utilized Mg II k 2796 Å (formed in the chromosphere), C II 1336 Å (formed in the lower TR), and Si IV 1403 Å (formed in the middle TR) lines for our study. In addition, the IRIS slit-jaw images (SJIs) were taken with the filters of SJI 2796 Å and SJI 1330 Å. The spatial pixel size is 0.33", and the time cadence is 18 s at both of the spectral data and SJIs. We used the IRIS level 2 data that are dark-current-subtracted, fielded, geometric-corrected, and wavelength-calibrated. Additionally, we used data from the Atmospheric Imaging Assembly (AIA; Lemen et al. 2012) on board the Solar Dynamics Observatory (SDO) to investigate higher atmospheric responses.

Figure 1. Images of the small sunspot taken by the FISS, IRIS, and the SDO at 17:30 UT on 2014 September 27. The white vertical line in the FISS Ca II-4 Å image indicates the location of the IRIS slit position, and the cyan cross symbols mark the selected position for detailed analysis in Figures 2 and 3.

Figure 1 shows the small sunspot at different solar atmospheric layers from the upper photosphere to the corona. The FISS Ca II and Hα raster images show the low atmosphere from the upper photosphere (line wings) to the chromosphere (line core). The IRIS SJI 2796 Å and SJI 1330 Å correspond to the chromosphere and the lower TR, respectively, and the AIA 171 Å corresponds to the upper TR and the corona. Alignment of the FISS and the IRIS data was carried out by using the FISS Ca II 8542 Å raster image (Figure 1, top center panel) and the IRIS SJI 2796 Å image (Figure 1, bottom left panel).

We inferred the line of sight (LOS) Doppler velocity by applying single Gaussian fit and the lambdameter method to the line profiles. Generally, Mg II and C II line profiles are central-reversed (double-peaked), but inside the sunspot, they are single-peaked and fitted well by the single Gaussian fits (Tian et al. 2014). Similarly, since the Ca II absorption line profiles in sunspot umbras have an emission core, the core of the line profile is appropriate for applying the single Gaussian fit. Thus, we applied the single Gaussian fits to the line profiles of the Ca II, Mg II, C II, and Si IV lines. Whereas, in the case of the Hα absorption line profile, we applied the lambdameter method, which calculates the Doppler velocity by determining the mid-
The remarkable finding of this study is that the redshifted feature abruptly showed up and the oscillations began immediately at around \( t = 10 \) minutes, and the Doppler velocity sharply increased, reaching its peak value of 7.4 km s\(^{-1}\) at \( t = 16.5 \) minutes. Meanwhile, in the \( \text{Ca}\II \) and \( \text{Si}\IV \) lines, the event began at \( t = 14 \) minutes and the Doppler velocity sharply increased, reaching their peaks at \( t = 16 \) minutes with values of 17.4 km s\(^{-1}\) and 24.7 km s\(^{-1}\), respectively. We expect the true Doppler velocity of the downflow may be a little higher than these values since the single Gaussian fits may include a stationary component as well.

We find several properties of the oscillations that occurred after the downflow event from Figure 3. The oscillations are seen in all of the lines, and it implies that the oscillations are detected in a wide range of temperatures, i.e., from the chromosphere temperature (10\(^4\) K) to the middle TR temperature (10\(^4.9\) K). The amplitude of the oscillations is about 2 km s\(^{-1}\) in most of the lines and slightly decreases with time.

### 3. RESULTS

The remarkable finding of this study is that the redshifted feature abruptly showed up and the oscillations began immediately at around \( t = 10 \) minutes, and the Doppler velocity sharply increased, reaching its peak value of 7.4 km s\(^{-1}\) at \( t = 16.5 \) minutes. Meanwhile, in the \( \text{Ca}\II \) and \( \text{Si}\IV \) lines, the event began at \( t = 14 \) minutes and the Doppler velocity sharply increased, reaching their peaks at \( t = 16 \) minutes with values of 17.4 km s\(^{-1}\) and 24.7 km s\(^{-1}\), respectively. We expect the true Doppler velocity of the downflow may be a little higher than these values since the single Gaussian fits may include a stationary component as well.

We find several properties of the oscillations that occurred after the downflow event from Figure 3. The oscillations are seen in all of the lines, and it implies that the oscillations are detected in a wide range of temperatures, i.e., from the chromosphere temperature (10\(^4\) K) to the middle TR temperature (10\(^4.9\) K). The amplitude of the oscillations is about 2 km s\(^{-1}\) in most of the lines and slightly decreases with time.
From the wavelet analysis of the power spectrum (Torrence & Compo 1998), we find that the dominant period of the oscillations is initially 2.7 minutes and gradually increases to 3.3 minutes. These properties of the oscillations are well identified in the MgII line, and other lines as well. In the case of the CaII and CII lines, the oscillation patterns are very similar to those of the MgII line. The SiIV line also shows the same oscillations, but the oscillation patterns are less conspicuous in the SiIV line. The amplitude of the Hα Doppler velocity appears smaller than that of the other four lines, which may be because the lambdameter method underestimates Doppler velocity of features in the upper chromosphere. Nevertheless, we can still identify the oscillation patterns in the Hα line.

Another interesting phenomenon is the coherency of the LOS Doppler velocity patterns in the five different spectral lines after the downflow event (see Figure 3). Before the event, each line shows its common velocity reflecting Doppler velocity at each line formation temperature. For example, in the MgII line, upward motion is dominant, and in the SiIV line, downward motion is dominant. After the event, however, every line shows a similar pattern of the Doppler velocity. The amplitudes of each line are almost the same, and there are no clear phase differences among the five spectral lines.

In Figure 4, the downflowing plasma is identified in the Hα +0.5 Å image, and we find associated transient brightening in the IRIS SJI 1330 Å. In the Hα+0.5 Å image, we can see an elongated absorption feature in the center of the image. The feature is also prominent in the Hα LOS velocity map with positive velocity. As seen in the Hα+0.5 Å image and the LOS velocity map, the downflow plasma is coming from the outer part of the sunspot to the umbra. During the downflow event, a brightening is identified in the IRIS SJI 1330 Å marked with a white arrow. The brightening corresponds to the end of the Hα flow, and the size of the brightening is about 3″. As seen in the Figure 2(d), the bright feature lasted about three minutes.

On the other hand, there is no associated brightening in the EUV images. In the SDO/AIA 171 Å images in Figure 4 and other EUV images, we cannot find any cospatial and cotemporal brightening associated with the flow identified in the Hα+0.5 Å image. This means that the temperature of the plasma downflowing along the magnetic fields is not enough to emit EUV light. As a matter of fact, we find a dark elongated feature that is located on the position of the Hα flow, and it also corresponds to the elongated bright features in the IRIS SJI 1330 Å.

4. DISCUSSION

For the first time, we detected impulsively generated three-minute oscillations above a sunspot in the chromospheric and TR lines. These oscillations are distinct from the three-minute umbral oscillations that exist persistently (e.g., Brynildsen et al. 1999). The oscillations we detected were driven by a strong downflow event above a sunspot. The downflow event suddenly appeared in the Hα, CIII, and SiIV lines, and then the oscillations were identified in all of the lines. The amplitudes of the Doppler velocity oscillations were about 2 km s⁻¹, and gradually decreased with time. In addition, the oscillation period was initially 2.7 minutes, and gradually increased to 3.3 minutes. Note that the Doppler velocity oscillations showed a similar behavior in all of the lines after the downflow event. That is to say, the amplitudes of the oscillations were the same values, and there were no evident phase differences among the five lines. We also found that a
transient brightening in the IRIS SJI 1330 Å image corresponds to the footpoint of the downflowing material shown in the Hα +0.5 Å image.

The characteristics of the downflowing material are similar to those of sunspot plumes to a certain degree. Sunspot plumes are generally located above sunspots and have downflows of $20-30 \text{ km s}^{-1}$ (Maltby et al. 1999; Brynildsen et al. 2001; Brosius 2005). They flow from outside the sunspots toward the umbra due to a gas pressure difference (Doyle & Madjarska 2003). In addition, it has been reported that plumes are identified in EUV lines formed at TR temperatures of $5.2 \leq \log T (\text{K}) \leq 5.9$ (Brosius 2005). However, the downflowing material we observed is found in the Hα line, and only the footpoint part of the material is identified in the FUV line of IRIS SJI 1330 Å. Since the downflowing material is identified in the Hα line and not in the EUV lines, it may imply that the temperature of the material is lower than that of the typical sunspot plumes.

We conjecture that the three-minute oscillations we observed represent gravity-modified acoustic waves generated by an impulsive disturbance (Lamb 1909; Kalkofen et al. 1994; Chae & Goode 2015). The well-known work of Fleck & Schmitz (1991) demonstrated that three-minute oscillations arise as a natural response of the atmosphere excited by a five-minute piston motion in the lower boundary. Chae & Goode (2015) regarded this phenomenon as a consequence of the sudden setup of the driving motion that is a sort of impulsive disturbance from the initial equilibrium. According to Chae & Goode (2015), an impulsive disturbance in a gravitationally stratified medium generates two packets of dispersive acoustic waves, i.e., high-frequency waves and low-frequency waves. Since the group speeds of the high-frequency waves are higher than those of the low-frequency waves, they propagate faster than the low-frequency waves. For this reason, at a fixed position, the observed oscillation frequency changes from high to low values, or the oscillation period changes from short to long values. In addition, since the waves carry energy away, the amplitude of the oscillations decreases with time. These theoretical characteristics are consistent with our findings of the occurrence of the oscillations, the increase of the oscillation period, and the decrease of the oscillation amplitude. Indeed, the waves generated in a gravitationally stratified medium are dispersive, and they propagate out of the source region (Kalkofen et al. 1994; Chae & Goode 2015). Thus, there should be a phase difference of the velocity oscillations when they are observed in two different atmospheric layers. Additionally, the amplitudes of the velocity oscillations may be different in the two different layers, since they are affected by physical conditions of the layer that they belong to.

One may wonder why the oscillations in our data show a similar behavior in all of the chromospheric ($\text{Ca} \, \text{ii}, \, \text{H} \alpha, \, \text{Mg} \, \text{ii}$) and the TR lines ($\text{C} \, \text{ii}, \, \text{Si} \, \text{iv}$). A possible explanation is that the five spectral lines were formed in the same atmospheric layer. The bright feature seen in the IRIS SJI 1330 Å corresponds to the end of the downflow material. It indicates that the footpoint of the flow rooted in the lower atmosphere (chromosphere) is heated up to middle TR temperatures ($10^{4.9} \text{ K}$), probably by the gravitational energy of the material flowing along the flux tube.

The TR temperature plasma, however, may be far from ionization equilibrium. Hence, all the neutrals and singly ionized elements will get ionized in a short time because of the enhanced temperature and density (Carlsson & Stein 2002). The TR temperature plasma, however, may still contain some amount of neutrals and singly ionized elements reproduced by the recombination of ions and electrons. The spectral lines of these species may display the same dynamical property as the other TR lines, and therefore the oscillations we identified in the five spectral lines may show high similarities.

Our results suggest that impulsive events can drive three-minute oscillations in the chromosphere. Among them we observed a transient downflow event that occurred in the chromospheric parts of magnetic loops anchored inside the sunspot. Since the solar chromosphere displays a variety of impulsive events, we expect that all the events may significantly contribute to the generation of oscillations and waves in the solar chromosphere.
