The DREAM complex represses cell cycle genes during quiescence through scaffolding MuvB proteins with E2F4/5 and the Rb tumor suppressor paralog p107 or p130. Upon cell cycle entry, MuvB dissociates from p107/p130 and recruits B-Myb and FoxM1 for up-regulating mitotic gene expression. To understand the biochemical mechanisms underpinning DREAM function and regulation, we investigated the structural basis for DREAM assembly. We identified a sequence in the MuvB component LIN52 that binds directly to the pocket domains of p107 and p130 when phosphorylated on the DYRK1A kinase site S28. A crystal structure of the LIN52–p107 complex reveals that LIN52 uses a suboptimal LxSxExL sequence together with the phosphate at nearby S28 to bind the LxCxE cleft of the pocket domain with high affinity. The structure explains the specificity for p107/p130 over Rb in the DREAM complex and how the complex is disrupted by viral oncoproteins. Based on insights from the structure, we addressed how DREAM is disassembled upon cell cycle entry. We found that p130 and B-Myb can both bind the core MuvB complex simultaneously but that cyclin-dependent kinase phosphorylation of p130 weakens its association. Together, our data inform a novel target interface for studying MuvB and p130 function and the design of inhibitors that prevent tumor escape in quiescence.

Keywords: cyclin-dependent kinases; DREAM complex; MuvB; cell cycle; phosphorylation; retinoblastoma-like proteins p107 and p130

Supplemental material is available for this article.

Received December 18, 2014; revised April 3, 2015.

Cell cycle exit is a critical process for differentiation and tumor prevention, and cancer cells often have lesions in pathways that control temporary [quiescence] or permanent [senescence] exit. Understanding fundamental mechanisms of cell cycle exit is critical for understanding development and ultimately designing therapeutic strategies that manipulate exit pathways for halting tumor proliferation. Quiescence has recently been shown to be dependent on the highly conserved protein complex known as DREAM (Litovchick et al. 2007, 2011; Sadasivam and DeCaprio 2013). Genetics experiments in model organisms reveal an essential role for DREAM components in differentiation, cell proliferation, and tumor suppression [Korenjak et al. 2004; Lewis et al. 2004; Harrison et al. 2006; Litovchick et al. 2007; van den Heuvel and Dyson 2008; Reichert et al. 2010]. DREAM-deficient mice die shortly after birth with bone developmental defects that result from aberrant chondrocyte differentiation (Forristal et al. 2014). In human cell culture, DREAM is assembled upon serum starvation in an experimental state of quiescence, and disruption of the DREAM complex drives cells back into the cell cycle despite environmental cues to arrest [Pilkinton et al. 2007; Schmit et al. 2007; Litovchick et al. 2011].

Chromatin immunoprecipitation (ChiP) has located DREAM proteins at a majority of E2F and cell cycle homology region (CHR) promoters in human cells, and gene expression analysis has implicated DREAM as a repressor of cell cycle genes (Litovchick et al. 2007, Schmit et al. 2007; Muller et al. 2012). The mechanism of how DREAM regulates transcription has not been elucidated, but it is clear that its central components scaffold a number of key cell cycle transcription factors, including E2F4/5, B-Myb, FoxM1, and the Rb tumor suppressor family paralogs p107 and p130 [Korenjak et al. 2004; Lewis et al. 2004; Litovchick et al. 2007; Schmit et al. 2007; Sadasivam et al. 2012]. DREAM was originally isolated through biochemical purification in flies and worms.
and in each case, the complex contained multivulval class B protein homologs LIN9, LIN37, LIN52, LIN54, and RBAP48 (mammalian protein names), which together are called the MuvB subcomplex (Korenjak et al. 2004; Lewis et al. 2004; Harrison et al. 2006; van den Heuvel and Dyson 2008). The biochemical functions of these proteins are unknown, with the exception of RBAP48 and LIN54, which bind histones and DNA, respectively (van den Heuvel and Dyson 2008; Sadasivam and DeCaprio 2013).

In mammalian cells, MuvB associates with p130–E2F4/5 to form DREAM in G0 and early G1 and associates with B-Myb during S phase to form the Myb–MuvB (MMB) complex [Pilkinton et al. 2007; Schmit et al. 2007; Litovchick et al. 2011; Sadasivam et al. 2012]. While DREAM represses gene expression, MMB activates late cell cycle genes during S phase and G2 both with and without FoxM1 (Georlette et al. 2007; Litovchick et al. 2007; Pilkinton et al. 2007; Schmit et al. 2007; Wen et al. 2008; Sadasivam et al. 2012). MuvB thus has an intriguing role in unifying cell cycle-dependent gene expression; however, the mechanisms by which DREAM and MMB–FoxM1 are assembled and regulated to carry out their specific functions are not well understood. DREAM formation requires the phosphorylation of MuvB protein LIN52 at serine residue 28 [phosS28] by the DYRK1A kinase (Litovchick et al. 2011). The phosphorylation of MuvB protein LIN52 at serine residue 28 [phosS28] by the DYRK1A kinase (Litovchick et al. 2011). To determine whether LIN52 directly associates with p130, we performed a series of binding experiments with recombinant, purified proteins. We first purified full-length GST-LIN52-HIS and GST-p130, both expressed in Sf9 cells, and found coprecipitation using Ni2+ affinity resin (Fig. 1A). Electrospray mass spectrometry indicated that the LIN52 purified from Sf9 cells is phosphorylated [Supplemental Fig. 1A,B]. Given the observation that the binding appears substoichiometric, we postulated that p130 is heterogeneously phosphorylated in Sf9 cells, as previously observed for Rb [Burke et al. 2010], and that phosphorylation weakens LIN52 association. We treated p130 with λ phosphatase during purification and observed a band shift on a Phos-tag SDS-PAGE gel (Supplemental Fig. 1C). After treatment with and subsequent separation from phosphatase, the p130–LIN52 complex stability appears increased (Fig. 1A).

We next tested whether phosphorylation of S28 in LIN52 is necessary for its direct interaction with pocket proteins. p130 and p107 pocket domains were expressed and purified from Escherichia coli without post-translational modifications. These constructs (p107AL and p130AL) each lack two internal loops and are similar to crystallized Rb constructs that maintain E2F and viral protein-binding activity [Lee et al. 1998; Balog et al. 2011]. We also purified LIN52 constructs expressed in Sf9 cells containing the N-terminal domain [residues 13–45; LIN5213–45]. We found that LIN5213–45 is sufficient for direct association with the p130 and p107 pocket domains. An S28A mutation in LIN5213–45 or λ phosphatase treatment reduces binding to p130 and p107 (Fig. 1B,C), demonstrating the importance of S28 phosphorylation for formation of the complex.

The pocket domain contains two protein interaction interfaces: the LxCxE cleft and the E2F transactivation domain (E2FTD)-binding site [Lee et al. 1998, 2002; Xiao et al. 2003; Dick and Rubin 2013]. The LxCxE cleft binds viral and endogenous proteins containing an LxCxE motif [x is any amino acid, and φ is a hydrophobic amino acid] [Jones et al. 1990; Lee et al. 1998; Singh et al. 2005]. A p107 cleft mutant fails to assemble DREAM in vivo (Forristal et al. 2014) and we therefore hypothesized that LIN52 directly binds to the LxCxE cleft rather than the E2FTD site. In support of this hypothesis, a purified p107 pocket domain cleft mutant (I931A, N935A, and V939A) fails to bind LIN52 (Fig. 1D).
The DREAM complex is perturbed in cervical cancer cells infected with human papillomavirus type 16 (HPV16), and knockdown of the oncoprotein HPV16 E7 rescues DREAM assembly and promotes cell cycle arrest (Nor Rashid et al. 2011). To determine whether HPV16 E7 can inhibit the direct LIN52 association with the p130 pocket domain, we used a fluorescence polarization (FP) competition assay. A LIN5212–34;phosS28 peptide was labeled with a tetramethylrhodamine (TMR) dye and mixed with increasing amounts of p130ΔL to obtain FP saturation curves. Addition of E721–29 peptide to the binding reaction shifted the curves such that p130ΔL appeared to bind with weaker affinity (Fig. 1E). We then quantified the E7 peptide inhibition [Kᵢ = 170 ± 50 nM] by displacing labeled LIN5212–34;phosS28 peptide in the FP assay (Fig. 1F). E721–29 contains an LxCxE motif and inhibits LIN52 from interacting with p130, indicating that E7 disrupts DREAM by competitive inhibition at the LxCxE cleft of p130.
Crystal structures of LIN52–p107 and E7–p107 complexes

To identify the molecular interactions involved in DREAM assembly and oncoprotein-facilitated disruption, we solved the crystal structures of the p107ΔL pocket domain bound to a phosphorylated synthetic LIN52 peptide [LIN5212–34,phosS28] at 2.3 Å and bound to an E7 [E721–29] peptide at 2.2 Å (Fig. 2; Table 1). The structures reveal that the overall fold of the p107 pocket domain is similar to that of Rb, consisting of two helical subdomains called the A and B boxes. Each subdomain contains a five-helix cyclin fold flanked by additional helices that form the A–B interface or the LxCxE interface or cover hydrophobic surfaces. As with previous Rb pocket domain structures (Lee et al. 1998, 2002; Xiao et al. 2003; Balog et al. 2011), most residues in the central loop between the two subdomains were left out of the crystallized construct, and the residues that remain are not visible in the electron density.

Structural alignment of the p107 and Rb pocket domains (Protein Data Bank [PDB]: 3POM) shows a root mean square deviation (RMSD) in the Cα position of only 1.2 Å [Supplemental Fig. 2A]. While most secondary structural elements compare, relative to Rb, the p107 A-box has two additional small helices (α4’ and α10’). These helices consist of sequences for which the corresponding electron density in Rb was not observable. α10’ occurs at the C terminus of the A-box and creates additional A–B interface contacts through packing against α11. The E7 peptide binds to the LxCxE cleft in the B-box of p107 as previously observed in the Rb–E7 complex structure (Fig. 2, Supplemental Fig. 2B; Lee et al. 1998). The similar specific contacts made are consistent with the high sequence homology between Rb and p107 within the LxCxE cleft.

In the p107ΔL–LIN5212–34,phosS28 structure, LIN52 binds at the LxCxE cleft, consistent with our coprecipitation experiments. The LIN52 peptide binds with an LxSxExL [residues 18–24] motif and makes a set of interactions similar to that of the E7 peptide [Figs. 2, 3A; Supplemental Fig. 3]. However, several striking differences arise from the presence of the more polar hydroxyl group in the LIN52 serine side chain. S20 occupies the place in the sequence analogous to that of the cysteine in the canonical E7 peptide LxCxExφ motif. C24 in the E7 peptide fits in a hydrophobic pocket formed by F861 and Y849. In contrast, S20 in LIN52 makes hydrogen bonds with the K853 and Y849 side chains. The positions of both the F861 and Y849 side chains are changed in the LIN52 complex such that the F861 phenyl ring is flipped out toward solvent. Whereas the E7 peptide E26 side chain makes hydrogen bonds with the backbone of F861 and Q862, the LIN52 E22 side chain is occluded from the analogous position by the flipped-out F861 side chain. These structural differences suggest that the LIN52 serine-containing motif binds with weaker affinity than the canonical E7 motif.

The S28 phosphoserine side chain in LIN52 binds a positively charged pocket in p107 consisting of R869, S876, Y879, and R880 (Fig. 2). These p107 side chains are highly conserved in p107 and p130 paralogs but not in Rb (Fig. 3A). Rb notably has F739 at the Y879 position in p107 and lacks the phenolic hydroxyl group that hydrogen-bonds with the LIN52 phosphate. The lack of the phosphate-binding pocket in Rb supports and explains previous observations that the DREAM complex does not assemble.
with Rb [Litovchick et al. 2007; Pilkinton et al. 2007; Schmit et al. 2007; Forristal et al. 2014]. The intervening amino acids between the LxSxExL sequence and phosS28 loop out from the p107 domain and do not make any direct contacts (Fig. 2). We also solved a crystal structure of p107Δ in complex with a mutant peptide (LIN5212–34; P29A; phosS28) that binds with higher affinity (Tables 1, 2). The electron density corresponding to the LIN52 peptide is stronger in this structure and allows for observation of additional interactions between W32 in LIN52 and E863, M865, R869, and Y879 in p107 (Supplemental Fig. 3).

While p107 and p130 loss in genetic models does not readily lead to tumors, there is evidence that p107 and p130 have tumor suppression function and can compensate for Rb loss in certain contexts [Dannenberg et al. 2004; Wirt and Sage 2010]. The cBioPortal for Cancer Genomics catalogs a number of missense and nonsense mutations in both p107 and p130 that occur in human cancer samples [Gao et al. 2013]. We found that 31 of the currently reported missense mutations for p107 are within the structured pocket domain (Supplemental Fig. 4). Based on the location of these residues in our crystal structure, we predict that 21 of these 31 mutations would destabilize the protein and likely result in functional loss. Three other mutations map to the E2F-binding surface based on the analogous Rb–E2F structure [Lee et al. 2002; Xiao et al. 2003]. Notably, two mutations [R880I and Y934C] and an analogous p130 mutation map to the LIN52 interface, and we found that these p107 mutations weaken the LIN5212–34; phosS28 peptide affinity (Supplemental Fig. 4). These observations support the idea that p107/p130-dependent growth control through both E2F inhibition and DREAM function plays an important role in tumor suppression.

**LIN52 S28 phosphorylation increases LxSxExL affinity**

Our structural data suggest that the LxSxExL sequence in LIN52 binds to the pocket domain with lower affinity than a canonical LxCxExL sequence and that phosphorylation increases affinity specifically in p107 and p130 to make a more stable complex. We tested these ideas by quantitatively measuring the affinity of different LIN52 peptides using isothermal titration calorimetry (ITC) [Fig. 3B; Supplemental Fig. 5]. LIN5212–34; phosS28 binds p107ΔL with an affinity of $K_d = 1.4 \pm 0.3 \mu M$ and p130ΔL with a similar affinity of $K_d = 1.0 \pm 0.1 \mu M$. An unphosphorylated LIN5212–34 peptide binds p107ΔL with weaker affinity [$K_d = 5.9 \pm 0.9 \mu M$]. Mutation of S20 to a cysteine

increases affinity for p107Δ (LIN52\textsubscript{12–34};S20C, \(K_d = 0.120 \mu M \pm 0.007 \mu M\)). The sensitivity of the canonical LxSxExL motif to a serine substitution has been observed previously in the case of the E7 peptide and Rb (Jones et al. 1990). We found that the LIN52\textsubscript{12–34};S20C affinity for p107Δ is similar to the affinity of the HPV16 E7\textsubscript{21–29} peptide for p107Δ (\(K_d = 0.16 \mu M \pm 0.04 \mu M\)). S28 phosphorylation in the context of the S20C mutation still increases affinity (LIN52\textsubscript{12–34};S20C;phosS28, \(K_d = 0.021 \mu M \pm 0.004 \mu M\)) such that it is tighter than the wild-type phosphorylated LIN52 sequence.

No binding was observable upon mixing of either the LIN52\textsubscript{12–34} or LIN52\textsubscript{12–34;phosS28} peptide with Rb. The LIN52\textsubscript{12–34;S20C} peptide (\(K_d = 0.3 \mu M \pm 0.1 \mu M\)) binds Rb with an affinity similar to that of p107; however, phosphorylation results in no additional increase in affinity (LIN52\textsubscript{12–34;S20C;phosS28}; \(K_d = 0.021 \mu M \pm 0.004 \mu M\)) such that it is tighter than the wild-type phosphorylated LIN52 sequence.

The fact that LIN52\textsubscript{12–34} and LIN52\textsubscript{12–34;phosS28} bind p107\textsubscript{mutant} with greater affinity than Rb suggests that p107-specific interactions other than the phosphate-binding pocket stabilize LIN52 association. One possible explanation observed in the crystal structure is the presence of I850 in p107. I850 contacts Y849 and stabilizes the Y849 position for hydrogen bonding to S20 in LIN52.
(Fig. 2). In contrast, G710 at the corresponding position in Rb cannot play the same stabilizing role and is likely a source of the lower Rb affinity for the noncanonical LxSxExL motif relative to p107/p130.

We tested the significance of the p107/p130-specific phosS28-binding site for DREAM assembly in cells (Fig. 3C). T98G cells were cotransfected with V5-tagged LIN52 and either wild-type HA-p130 or HA-p130 with a Y928F mutation (equivalent to Y879F in p107). LIN52-V5 was precipitated with an anti-V5 antibody, and we examined the amount of precipitated p130 by Western blot. LIN52 coprecipitated less Y928F mutant p130 protein than wild-type, supporting the requirement of an intact phosphate-binding pocket as observed in the crystal structure for DREAM assembly.

The LxSxExL sequence motif is critical for DREAM assembly

To explore further the important elements of the LIN52 LxSxExL-binding motif, we measured the affinity of different LIN52 peptides for the p107 pocket domain using the ITC assay (Table 2, Supplemental Fig. 5). Both the L18A (Kd = 14.9 μM ± 0.1 μM) and L24A (Kd = 7.4 μM ± 0.9 μM) consensus mutations in LIN52 reduce affinity. Although E22 in LIN52 does not make any interactions with p107 in the crystal structure (Fig. 2), we also found that an E22A mutation (Kd = 5.5 μM ± 0.1 μM) reduces affinity fourfold compared with wild type (Kd = 1.4 μM ± 0.8 μM). We suggest that, in solution, there is an alternate conformation in equilibrium that resembles the E7 peptide conformation but is less stable because of the buried S20 hydroxyl group.

We also measured the effects of moving the position of phosS28 relative to the LxSxExL motif. Addition of an alanine to the intervening three residues results in similar affinities (LIN52-34;P29A;phosS28, Kd = 1.7 μM ± 0.3 μM), while the peptide with A27 deleted binds with 10-fold tighter affinity (LIN52-34;A27, Kd = 0.126 μM ± 0.002 μM). This observation is consistent with a lack of interactions between the intervening sequence and pocket domain (Fig. 2). The tighter affinity of the shorter sequence may result from a reduced entropic penalty for binding. Many kinases phosphorylate substrates bearing an [S/T]/P motif, which include DYRK1A and the CDKs (Ubersax and Ferrell 2007). We tested a LIN52 phosS28 P29A mutant to determine whether p107 binding is also dependent on this motif. The mutant has a higher affinity (LIN52-34;P29A;phosS28, Kd = 0.035 μM ± 0.003 μM) than wild-type, suggesting that the proline is required for kinase recognition of S28 but is not preferred at this position for pocket binding.

To determine whether the p130 pocket association with the LIN52 LxSxExL motif is required for DREAM assembly in cells, we generated LIN52-HA-Flag mutants stably expressed in T98G cells. We then immunoprecipitated the Flag sequence and examined the coprecipitation of p130 by Western blot. When either E22 or S28 is mutated in LIN52, p130 binding is diminished, while binding of the MuvB proteins LIN37 and LIN9 is preserved (Fig. 3D). We also tested the stabilizing effect of an S20C mutant on the LIN52/p130 complex by coprecipitation (Fig. 3E). The LIN52-HA-Flag S20C mutant expresses at a higher level than wild type but does not coprecipitate a relatively greater amount of p130. However, when coexpressed with either E1A or large T-antigen viral proteins, both of which contain LxCxE complexes, LIN52 S20C does coprecipitate a relatively greater amount of p130 than wild type. We conclude that the wild-type sequence is sufficient to coprecipitate p130, but, when challenged with high-affinity viral proteins, the increase in affinity from the S20C mutation allows LIN52 to better compete with E1A and large T-antigen for p130 binding. This result emphasizes how the weaker LxSxExL motif in LIN52, even with the addition of S28 phosphorylation, enables DREAM disassembly by competitor viral oncoproteins.

B-Myb requires LIN52 to bind to MuvB but does not compete with p130

We next investigated the determinants of B-Myb binding to MuvB in order to compare the mechanisms of DREAM and MMB assembly. The evolutionarily conserved MuvB proteins in the Drosophila melanogaster DREAM complex were found to interact with the C terminus of B-Myb (Andrejka et al. 2011). To test whether this association is direct and conserved in the human proteins, we performed a series of precipitation experiments with recombinant B-Myb and MuvB proteins from SF9 cells (Fig. 4). We reconstituted the core MuvB subcomplex by coexpressing GST-LIN9-542, which lacks its poorly conserved and putative unstructured N terminus, along with full-length GST-LIN37, Strep-RBAP48, and GST-LIN52 as indicated. The purified complexes were then coprecipitated in the presence of the C terminus of B-Myb (GST-B-Myb642-700), and we found that GST-B-Myb642-700 binds the MuvB subcomplex only in the presence of LIN52 (Fig. 4A). However, full-length GST-LIN52-HIS, which is sufficient to coprecipitate p130 (Fig. 1A), is not sufficient to coprecipitate GST-B-Myb642-700 (Fig. 4B). We conclude that LIN52 is necessary but not sufficient for B-Myb binding. The requirement for LIN52 could result from direct B-Myb–LIN52 contacts or because LIN52 is necessary for a properly structured MuvB core.

We next tested whether p130 and B-Myb compete for access to MuvB or can both bind simultaneously. We found that Strep-tagged RbAP48 together with the other components of the MuvB subcomplex coprecipitates both GST-B-Myb642-700 and p130 pocket when all components are mixed in the same solution (Fig. 4C). Increasing the amount of p130 does not change the amount of GST-B-Myb642-700 that coprecipitates, consistent with a lack of competition (Fig. 4C). We also found that GST-B-Myb642-700 coprecipitates the p130 pocket if and only if the components of MuvB are present, demonstrating the presence of a complex that contains B-Myb642-700, the p130 pocket, and MuvB all together (Fig. 4D). Based on these observations that p130 and B-Myb can simultaneously bind MuvB and that they have different requirements for binding, we conclude that they have nonoverlapping
binding sites on the MuvB core. In order to demonstrate that full-length p130 and B-Myb associate together with MuvB in cells, we precipitated HA-Flag-B-Myb that is stably expressed in BJ-hTERT fibroblasts (Fig. 4E). We observed coprecipitation of endogenous LIN37 and p130 under conditions that support DREAM assembly, including serum starvation and Cdk4/6 inhibition with palbociclib [PD-0332991, Pfizer, Inc.]. Although we cannot rule out a direct association between full-length p130 and B-Myb in this experiment, the data are consistent with B-Myb coprecipitating p130 through a common MuvB core.
**CDK phosphorylation promotes DREAM disassembly**

Components of the MuvB complex fail to associate with p107 and p130 in cycling cells; however, the mechanism of DREAM inhibition upon exit from quiescence has not been elucidated. Considering that LIN52 is found phosphorylated and unphosphorylated at S28 when bound to B-Myb during S phase [Litovchick et al. 2011], dephosphorylation of LIN52 S28 is unlikely the primary mechanism promoting DREAM disassembly. Our result that B-Myb and p130 bind MuvB simultaneously also argues against a competitive mechanism for DREAM disassembly by which, upon expression, B-Myb displaces p130 from MuvB. Noting the coincident timing of Cdk activation and DREAM disassembly [Pilkinton et al. 2007], we tested directly whether Cdk activity correlated with p130 binding to MuvB. We found that the MuvB component LIN37 can coprecipitate a greater amount of p130 from the extracts of cycling T98G cells in the presence of the Cdk4/6 inhibitor (Fig. 5A). To observe the effect of Cdk inhibition on DREAM disassembly upon cell cycle entry, we released T98G cells from serum starvation and found that LIN37 coprecipitation of p130 persists to a greater extent in the presence of the Cdk4/6 inhibitor (Fig. 5B). In the absence of inhibitor, the loss of p130 coprecipitation, beginning at 10 h, correlates with the disappearance of the hypophosphorylated p130 form (the lower band in the gel). These results demonstrate that Cdk activity in cells inhibits p130-MuvB association.

We asked whether Cyclin D1 could inhibit DREAM assembly by directly competing with the LIN52 interaction at the p130 LxCxE cleft. Cyclin D1 was previously proposed to bind the LxCxE cleft in the Rb pocket domain [Dowdy et al. 1993]. However, we found in our FP assay (Fig. 1F) that a Cyclin D1 peptide does not displace LIN52 form p130ΔL. We also titrated the Cyclin D1 peptide bearing its LxCxE motif into p107ΔL and p130ΔL in the ITC assay and found no observable binding (Supplemental Fig. 5), suggesting that the Cyclin D1 sequence does not directly associate with the pocket domain. These results are supported by our ITC data and previous reports [Singh et al. 2005] that a hydrophobic residue is necessary at the downstream glutamic acid position in Cyclin D1.

We hypothesized that Cdk phosphorylation of p130/p107 inhibits the LIN52 interaction with the p130/p107 pocket domain. In support of this mechanism, we found that λ phastase treatment of the partially phosphorylated p130 purified from S9 cells increased LIN52-p130 complex stability in a qualitative coprecipitation assay (Fig. 1A). We quantified the effect of p130 phosphorylation on LIN52 binding using the FP assay described in Figure 1E. The TMR-LIN5212–34;phosS28 peptide was mixed with increasing amounts of GST-p130 purified from S9 cells without treatment, with phosphatase treatment, and with kinase treatment. While phosphatase treatment increases the affinity 3.5-fold, Cdk2 phosphorylation decreases the affinity nearly twofold, demonstrating that p130 phosphorylation weakens LIN52 binding [Fig. 5C]. The observation of a change in affinity upon treatment with either enzyme reflects the partial phosphorylation of GST-p130 purified from S9 cells.

Our structural observation that phosphorylated LIN52 binds p107/p130 at the LxCxE cleft suggests that Cdk phosphorylation events resulting in occlusion of the LxCxE-site would inhibit DREAM assembly. Studies of inactive Rb have revealed phosphorylation-induced structural changes that block the LxCxE cleft [Rubin et al. 2005; Burke et al. 2012; Rubin 2013]. We considered one mechanism in which phosphorylation of conserved sites in the linker between the N-terminal [RbN] and pocket domains results in RbN–pocket docking [Burke et al. 2012]. Alignment of the phosphorylated Rb structure with the p107–LIN52 complex suggests that an analogous closed conformation in p107/p130 would inhibit LIN52 binding [Fig. 5D]. In the Rb structure, residues in RbN form hydrogen bonds and salt bridge interactions with Rb pocket residues; the homologous residues in the p107 pocket domain contact the LIN52 S28 phosphate in the structure presented here.

To determine whether Cdk phosphorylation disrupts the DREAM complex through phosphorylation of sites in the putative p107/p130 interdomain linker, we examined the effect of p130 T401A and T417A mutation on MuvB binding in cycling U2OS cells. We expressed LIN52 together with p130 wild type and the phosphosite mutant and found that LIN52 coprecipitates a greater amount of the T401A/T417A double mutant (Fig. 5E). We also found that the p130 double mutant can coprecipitate a greater amount of endogenous LIN37 than wild type [Fig. 5F]. In order to test the functional consequences of mutating Cdk sites, we transfected U2OS cells with wild-type p130 and the T401A/T417A phosphosite mutant and examined proliferation of cells using S-phase-specific Ki-67 staining similar to as previously described [Canhoto et al. 2000]. We found that the T401A/T417A mutant induces a more potent growth arrest than wild type, which is consistent with stabilization of the DREAM complex (Fig. 5G). T401 and T417 phosphorylation have also been shown to be relevant for regulation of E2F activity [Farkas et al. 2002]. Mutation of these sites may also influence p130–E2F4 affinity and contribute to the observed growth arrest by stabilizing E2F binding.

**Discussion**

Our structural and binding data support a model in which the DREAM complex is mediated by the direct association of LIN52 with the p107/p130 pocket [Fig. 5H]. Assembly is promoted by DYRK1A phosphorylation of S28 in LIN52, while disassembly is induced by Cdk phosphorylation of sites in p107/p130 that promote structural changes to occlude the LIN52-binding surface. B-Myb binding is dependent on LIN52 and other members of the MuvB core and can occur simultaneously with p107/p130 binding in our assays with recombinant protein and in cells under conditions in which B-Myb is ectopically expressed and
p130 is known to be hypophosphorylated. The fact that B-Myb and p130 are not found together in complexes purified from mammalian cells is likely due to the coincidence of B-Myb expression and p130 phosphorylation in those cells (Litovchick et al. 2007). Complexes were purified from Drosophila cells containing both Myb and Rbf and may point to a distinct mechanism of regulation in lower metazoans. The D. melanogaster Rbf sequences notably lack

Figure 5. p130 phosphorylation weakens LIN52 binding and DREAM activity. (A) T98G cells were incubated for 24 h in the presence or absence of the CDK4/6 inhibitor palbociclib. Binding of p130 to LIN37 was determined by coimmunoprecipitation with an anti-LIN37 antibody and detection of proteins in a Western blot. The band marked with an asterisk in the p130 input blot is a nonspecific band. (B) T98G cells were serum-starved for 72 h and then released with addition of 10% FBS in the absence or presence of the CdK4/6 inhibitor palbociclib. After harvesting cells at the indicated time points, extracts were immunoprecipitated with an anti-LIN37 antibody and probed for LIN37 and p130. The band marked with an asterisk in the p130 input blot is a nonspecific band. (C) FP binding assay of TMR-labeled LIN5212–34, phosS28 to GST-p130. The GST-p130 was purified from sf9 cells and used untreated (green line, circles), treated with λ phosphatase (yellow line, squares), and treated with Cdk2 kinase (blue line, triangles). Purified GST alone was used as a negative control (inverted triangles). The expected effect of enzyme treatment was corroborated with a Phos-tag gel (Supplemental Fig. 1C). (D) Overlay of the LIN5212–34,phosS28–p107 structure and phosphorylated RbN55–767 structure (PDB: 4ELJ). Residues in p107 that bind the S28 phosphate in LIN52 (rendered as transparent blue sticks) are analogous to residues in the Rb pocket domain that bind the docked RbN domain (pink) when Rb is phosphorylated. (E) U2-OS cells were transfected with LIN52-V5 and the wild-type or T401A/T417A (TTAA) mutant HA-p130. Extracts were immunoprecipitated with anti-V5 antibody, and the indicated proteins were detected by Western blot. (F) Same as in E except an anti-HA antibody was used for immunoprecipitation. (G) U2OS cells were cotransfected with wild-type or the T410A/T417A (TTAA) mutant of p130 and GFP as tracer. The expression of Ki-67 was determined by indirect immunofluorescence cell staining at 48 h after transfection. The graph shows the average values and standard deviations (error bars) of three replicate experiments in which at least 100 cells were counted per condition. The P-value evaluating statistical significance was calculated using a two-tailed Student’s t-test. (H) Model for DREAM complex disassembly and MMB complex assembly upon Cdk activation.
conserved phosphorylation sites equivalent to T401 and T417 in p130, which further points to their importance in disassociating p130 from MuvB.

LIN52 accesses the LxCxE cleft of the pocket domain using a noncanonical and nonoptimal LxSxExL motif in combination with phosphorylation at S28. The weak affinity of the LxSxExL sequence sensitizes the association to regulatory phosphorylation by DYRK1A. Kinase phosphorylation acts as a switch because it increases LIN52 binding to submicromolar affinity. We note that in contrast to higher orthologs, Caeorhabditis elegans LIN52 maintains the canonical, tight-binding LxCxE motif and lacks the equivalent DYRK1A consensus surrounding the S28 residue. We predict that DREAM in C. elegans is not regulated equivalently by phosphorylation, and LIN52 and LIN35 constitutively form a stable complex. The LIN52 sequence in D. melanogaster resembles our LIN52Δ−S28,ΔA27,phosS27 peptide, suggesting that Drosophila Rb proteins and LIN52 also form a highly stable, phosphorylation-dependent interaction.

The requirement for LIN52 is an important source of specificity for p107 and p130 in DREAM assembly. Unlike Rb, the p107 and p130 pocket domains contain the proper phosphate-binding site. Phylogenetic sequence analysis of pocket proteins suggests that Rb appears more recently than p107 and p130, which are closer in sequence to pocket proteins such as LIN35 and Rbf in lower metazoans (van den Heuvel and Dyson 2008; Sadasivam and DeCaprio 2013). It is not clear then why Rb evolved such that it does not bind MuvB, although one possibility is that the LxCxE cleft in Rb must be reserved for some alternate unique function.

Despite their diverse cellular roles, the universal biochemical function of pocket proteins is to assemble protein complexes (Cobrinik 2005; Dick and Rubin 2013). It is estimated that several hundred proteins interact with Rb and its pocket protein paralogs, and the LxCxE cleft has been described as the key interface for these complexes (Morris and Dyson 2001). The crystal structure presented here of the p107−LIN52 complex provides the first structural insights into how cellular proteins contact the cleft. It implicates the LxSxExLxxxS sequence as a novel binding motif that can be regulated by phosphorylation. We searched the Scansite 3 server (Obenauer et al. 2003) to identify other potential p107/p130-binding partners that use this motif and the motifs identified in our binding studies that bind the novel phosphate-binding pocket. We identified 203 proteins that matched our motifs, although only 13 are known to be phosphorylated on the consensus serine (Supplemental Table 1).

Cdk phosphorylation has been well characterized as a mechanism for inactivating pocket proteins, and both structural and functional studies have implicated the effects of phosphorylation on inhibiting pocket protein interactions (Cobrinik 2005; Rubin 2013). Our results here further support phosphorylation of p107/p130 as a mechanism of inactivating the DREAM complex by dissociating pocket proteins from the MuvB core. Mutation of conserved Cdk sites T401 and T417 enhances the growth arrest properties of p130 and stabilizes the DREAM complex [Fig. 5]. Structural and sequence comparisons between p107/p130 and Rb suggest that a conserved closed conformation that occludes the LxCxE cleft is induced by phosphorylation. We note that additional Cdk sites in p107/p130 may contribute to inhibition of LIN52 binding and that phosphorylation may also contribute to DREAM dissociation by inhibiting p107/p130 association with E2F proteins.

It has been suspected that cancer cells can in certain contexts avert the effect of cytotoxic treatments by entering quiescence. As an important mediator of cell cycle exit, DREAM may be an important additional target during chemotherapy. For example, cells from gastrointestinal stromal tumors enter quiescence following treatment with imatinib, and inhibition of DREAM assembly through genetic knockdown alternatively induces apoptosis (Boichuk et al. 2013). Our structural characterization of LIN52 association with p107 suggests that inhibitors of protein interactions at the LxCxE cleft in pocket proteins would likely block DREAM function in vivo. It is encouraging that only a short peptide corresponding to the E7 sequence is sufficient for inhibition of LIN52 association in vitro (Fig. 1F), and small molecule inhibitors of the E7 LxCxE–Rb interaction have been reported (Fera et al. 2012). Discovery of more potent chemical inhibitors of LxCxE–pocket binding may prove to be a viable strategy for preventing cancer cells from escaping to quiescence as a mechanism for surviving therapeutic treatment.

Materials and methods

Protein expression and peptides

A human Rb pocket with its loop deleted [residues N380–G581, K643–R787], a p107 pocket [T391–Q972], p107ΔL [T391−T599, N780−B887, K924−Q972], and p130ΔL [H424–D632, N828−K935, E999–Q1049] were expressed and purified from E. coli BL21 cells as GST fusion proteins. Cells were induced with 1 mM IPTG and grown overnight at 20°C. Lysates were first purified by G58B affinity chromatography. The elution fraction was then subjected to TEV protease cleavage and dialyzed overnight in 25 mM Tris, 200 mM NaCl, 1 mM DTT, and 0.5 mM EDTA (pH 8.0). The protein was then passed over G58B affinity resin again to remove free GST, concentrated, and stored in a buffer containing 20 mM Tris, 200 mM NaCl, 1 mM DTT, and 20% glycerol (pH 8.0).

LIN52, LIN37, RBBP48, LIN9, B-Myb, and full-length p130 were expressed and purified from S9 cells (Expression Systems) using baculovirus vectors. Proteins were purified as described above, and the GST-free samples were passed over a Superdex-200 column that was equilibrated in the dialysis buffer following TEV cleavage. p130 was phosphatase-treated with 1% phosphatase by mass using the manufacturer’s protocol (New England Biolabs). Cdk2 treatment was performed as described (Burke et al. 2010) except the Cdk2 activator Speedy was used instead of a cyclin activator. Following treatment, GST−p130 was separated from the enzymes using a Superdex-200 column.

The LIN52Δ−S28,phosS27 and E7−29−29 peptides used for crystallization were synthesized by BioPeptide LLC. The LIN52Δ−S28,phosS27 peptide and all other peptides used for ITC and the FP assay were synthesized by GenScript, Inc.
p107ΔL was prepared for crystallization by elution from a Superdex-75 column in a buffer containing 25 mM Tris, 500 mM NaCl, and 5 mM DTT (pH 8.0). LIN52ΔD12–34::phosS28 was added in threefold molar excess to 14 mg/mL p107ΔL, and E7ΔL was added in twofold molar excess to 12 mg/mL p107ΔL. After incubation for 30 min on ice, both complexes were crystallized by sitting-drop vapor diffusion at 4°C. Plates formed after 2 wk in 100 mM MES (pH 6.5), 1.6 M [NaH2]SO4, and 4% PEG 400 for the LIN52ΔD12–34::phosS28 complex and in 100 mM HEPES (pH 7.5), 1.7 M [NaH2]SO4, and 4% PEG 400 for the E7ΔL complex. Crystals were frozen in the proper well buffer with 20% ethylene glycol. Some crystals containing the LIN52ΔD12–34::phosS28 peptide were soaked with 20-fold molar excess of the P29A mutant peptide before freezing.

Data were collected at the Advanced Photon Source, Argonne National Laboratory at Beamline 23-IDB. Diffraction spots were integrated using MOSFLM (Leslie 2006), and data were merged and scaled using Scala (Bailey 1994). Phases were first solved for the E7ΔL complex by molecular replacement using Phaser (McCoy et al. 2007). A homology model of p107ΔL, which was constructed using the Rb pocket domain (PDB: 3POM), was used as a search model. p107ΔL complexes with LIN52 peptides were then solved using the E7ΔL complex as a search model, as the crystal form was slightly different. Peptides were built with Coot (Emsley and Cowtan 2004), and the models were refined with PHENIX (Adams et al. 2010). Coordinates and structure factors have been deposited in PDB for the structures with the E7ΔL, LIN52ΔD12–34::phosS28, and LIN52ΔD34::P29A::phosS28 peptides under accession codes 4YOZ, 4YOS, and 4YOO, respectively.

Coprecipitation assays

For assays with recombinant protein, 50 μg of each indicated protein was incubated with 15 μL of either GST resin, Streptactin resin, or nickel sepharose Excel resin (all from GE Healthcare) in a buffer containing 25 mM Tris, 150 mM NaCl, and 1 mM DTT (pH 8.0) for 30 min on ice. The resin was washed three times using the same buffer or with the addition of 20 mM imidazole and was eluted using 30 μL of elution buffer containing 25 mM Tris, 200 mM NaCl, and 1 mM DTT (pH 8.0) with either 20 mM glutathione, 400 mM imidazole, or 10 mM desthiobiotin as needed. Under these conditions, we did not find that GST mutants as described (Farkas et al. 2002). Cells were extracted using EBC lysis buffer (50 mM Tris, 150 mM NaCl, 0.5% NP-40 at pH 7.4), immunoprecipitated, and subjected to Western blot analysis as described previously (Litovchick et al. 2007). Band intensities were quantified using ImageJ software.

Proliferation assay

U2OS cells were seeded onto six-well plates at 2 × 10⁵ cells per well and transfected with pcDNA3.1 vectors encoding p130 constructs and GFP. The p130 vector was transfected at a 4:1 molar ratio relative to the GFP vector. Forty-eight hours after transfection, the cells were trypsinized and seeded in triplicate onto six-well plates containing glass coverslips and allowed to attach for 24 h. Proliferating GFP-positive and GFP-negative cells were counted by indirect immunofluorescence staining using anti-Ki67 (Millipore) antibodies as described in Canhoto et al. (2000). To determine the fraction of proliferating cells in each sample, the number of Ki67-positive cells was determined in at least 100 cells per condition using an EVOS fluorescent microscope (AMG advanced microscope group) and a 20× objective. U2OS cells were chosen for this assay because they have intact Rb family members and are highly proliferative and thus sensitive to increases in the DREAM arrest activity.

Calorimetry

Equilibrium dissociation constants for p107, p130, Rb, LIN52, and E7 binding were obtained using ITC with the Micro Cal VP-ITC system (GE Healthcare). Peptides and proteins were dialyzed overnight and titrated into a buffer containing 25 mM Tris, 200 mM NaCl, and 5 mM BME (pH 8.0) at 15°C. Because of the difficulty in accurately determining peptide concentration, the peptide concentration was adjusted in the fitting such that all of the stoichiometry values were equal to 1.0.

FP assay

TMR-LIN52ΔD12–34::phosS28 was mixed at 20 nM with p130ΔL GST-p130 in a buffer containing 40 mM Tris, 150 mM NaCl, 1 mM DTT, and 0.1% Tween (pH 8.0). Twenty microliters of the reaction was used for the measurement in a 384-well plate. FP measurements were made in triplicate using a Perkin-Elmer EnVision plate reader, and reported FP values were determined using instrument software. Error bars in the plots show standard deviations for the three measurements of each point, while the reported errors in Kd and Kf are errors derived from curve fits. We note that absolute Kf measurements were typically tighter using the FP assay compared with ITC and suggest that this difference may be due to the presence of the dye in the peptide or other subtle differences in experimental conditions.

Acknowledgments

We thank Fred Dick for the DREAM-binding deficient p107 mutant plasmid. This work was supported by a grant from the National Institutes of Health (R01CA132685) to S.M.R.
