Nonequilibrium dynamics of a pure dry friction model subjected to coloured noise

Paul M. Geffert and Wolfram Just
School of Mathematical Sciences, Queen Mary University of London, London E1 4NS, United Kingdom

We investigate the impact of noise on a two-dimensional simple paradigmatic piecewise-smooth dynamical system. For that purpose we consider the motion of a particle subjected to dry friction and coloured noise. The finite correlation time of the noise provides an additional dimension in phase space, causes a nontrivial probability current, and establishes a proper nonequilibrium regime. Furthermore, the setup allows for the study of stick-slip phenomena which show up as a singular component in the stationary probability density. Analytic insight can be provided by application of the unified coloured noise approximation, developed by Jung and Hänggi [1]. The analysis of probability currents and of power spectral densities underpins the observed stick-slip transition which is related with a critical value of the noise correlation time.

PACS numbers:

I. INTRODUCTION

Piecewise-smooth dynamical systems have attracted a lot of interest in the last decade. They are widely used to model switching or impact behaviour in many different areas of science i.e. as biology, engineering, physics or mathematics [2–6]. Systems with dry (or Coulomb) friction are prominent examples in the context of piecewise-smooth models [7]. The main feature of this type of friction is that an applied force has to overcome a certain threshold to move an object (sliding), otherwise the object rests (sticking) [8]. This behaviour is usually modelled by a sign-function and allows a simple macroscopic description for systems where solid-solid interactions are important, e.g. as for stick-slip dynamics [9, 10]. Adding noise to the dynamical equations of a piecewise-smooth system opens a whole new area of research, which is still in its infancy. The interplay of dry friction and random forces has been reported in [11–13]. Exact solutions are known for a few piecewise-smooth stochastic models, where e.g. the propagator can be obtained for the case of pure dry friction [14, 15] or in connection with Laplace transforms [16]. Other analytical results are available in the framework of path integrals and weak noise approximations [17–19] or first passage time problems [20]. Whereas the aforementioned studies are dealing with Gaussian white noise, models with Non-Gaussian noise and dry friction have been investigated as well [21–23]. The features of systems with dry friction subjected to random forces have also been observed in experimental setups [24–28]. From a more rigorous mathematical point of view, the impact of a stochastic perturbation on a piecewise-smooth dynamical system has been considered in [29, 30].

A profound understanding of the impact of noise on piecewise-smooth dynamical systems is desirable from an intrinsic theoretical perspective, and will contribute as well to relevant experimental issues. For instance, nonequilibrium properties of granular media is a topical subject, see e.g. [31] for recent experimental results. The corresponding theoretical modelling uses granular material as a nonequilibrium heat bath, and studies the impact on devices subjected to dry friction. Localisation phenomena of the velocity and intermittent dynamics are consequences of the underlying stick-slip dynamics [32–34]. Realistic theoretical models are fairly complicated so that only very limited analytic insight can be obtained.

The inclusion of a finite correlation time of the noise is a simple way to emulate nonequilibrium properties of a heat bath. If the correlation time of the noise is of the same order as the characteristic time scale of the system a correlated noise (or coloured noise) is required [35]. Analytical treatments of coloured noise are hampered by the lack of detailed balance. In this context the so-called unified coloured noise approximation (UCNA) has been developed by Jung and Hänggi to obtain analytic expressions for the stationary probability density [1]. Coloured noise has been studied in many different contexts, e.g. magnetic resonance systems [36] or neurodynamics [37].

The purpose of our contribution is twofold. We want to investigate the impact of noise on piecewise-smooth dynamical systems in a simple setup which allows for a partial analytic treatment. Furthermore, the nonequilibrium aspects, the occurrence of stationary probability currents, and transition phenomena will be a crucial part of our investigations. This paper is organized as follows: Section II introduces the pure dry friction model subjected to coloured noise. The stationary behaviour of the model is investigated in Section III. Analytic expressions for the velocity distribution will be derived together with an asymptotic expression for the two-dimensional stationary distribution. Analytic results are supported by numerical simulations for the density and for the stationary probability current. Dynamical properties such as the power spectral density and the distributions of sliding and sticking events are elaborated on in Section IV. We conclude our studies in Section V.

II. THE MODEL

We consider the simplest two-dimensional case of a piecewise-smooth stochastic system, which does not obey detailed balance. To motivate our considerations let us
recall the one-dimensional motion of a particle subjected to white noise. With a slight abuse of notation the corresponding Langevin equation governing the velocity reads
\[ \dot{v}(t) = -\sigma_0(v(t)) + \xi(t), \] (1)
where \( \xi(t) \) denotes a white Gaussian noise with correlation function \( \langle \xi(t)\xi(s) \rangle = \delta(t-s) \) and \( \sigma_0(v) = \text{sign}(v) \) contains the deterministic part caused by Coulomb friction. We have adopted units such that the noise intensity and the dry friction coefficient have been normalized to one. Eq.(1) is not well defined at \( v = 0 \). One could cure such an inconsistency by considering the Coulomb friction as the limiting case of the regular drift \( \sigma_\varepsilon(v) = \tanh(v/\varepsilon) \) for \( \varepsilon \to 0 \). Such niceties are not relevant for eq.(1) as the white noise is not a function with well defined finite values and the stochastic model in a strict sense is not pointwise defined. The formally written down Fokker-Planck equation with suitable matching conditions ensuring continuity of the density and continuity of the probability current captures all aspects of the dynamics and has been studied intensely in the literature, see, e.g., [12]. The deterministic part without noise requires a more careful approach in terms of piecewise-smooth dynamical systems [2], in particular, in the presence of a finite amplitude driving force where stick-slip transitions occur (cf. eq.(3)).

An obvious extension of the model described above, leading towards a two-dimensional stochastic nonequilibrium system, consists in studying the effect of coloured noise. To be precise we intend to replace the Gaussian white noise by an exponentially correlated Ornstein-Uhlenbeck process \( \eta(t) \), which is governed by the stochastic differential equation
\[ \dot{\eta}(t) = -\eta(t)/\tau + \xi(t)/\tau. \] (2)
The noise correlation time \( \tau \) will be the only effective parameter in our model. Since the process \( \eta(t) \) can be viewed as a continuous function some care is needed when introducing the dynamics of the particle. For forces smaller than the dry friction coefficient, \( |\eta| < 1 \), and \( v = 0 \) the particle will stick while otherwise the sliding dynamics is still described by the aforementioned equation of motion.

Thus we end up with
\[ \dot{v}(t) = \begin{cases} 0 & \text{if } v = 0 \text{ and } |\eta(t)| < 1 \\ -\sigma_0(v(t)) + \eta(t) & \text{otherwise} \end{cases} \] (3)
Alternatively we could use the regularized drift
\[ \dot{v}(t) = -\sigma_\varepsilon(v(t)) + \eta(t) \] (4)
illustrate the main phenomenon by time traces obtained from numerical simulations. Throughout all our numerical investigations we apply an Euler-Maruyama scheme with step size $h = 10^{-3}$ for different values of $\tau$. To take the discontinuity caused by dry friction into account (see eq.(3)) we set $v = 0$ for $|v| < 10^{-3}$ and $|\eta| < 1$, as the particle sticks in this case at the origin. Time traces from the simulations are shown in figures 1 - 3. At a scale of order one the effect of dry friction becomes visible for correlation times larger than $\tau = 0.1$. The particle sticks for considerable amounts of time at $v = 0$, as the stochastic force $\eta(t)$ is not large enough to move the particle. It is this stick-slip phenomenon and the related intermittent motion which will be at the centre of our studies, being the key signature of our piecewise-smooth stochastic model.

The observed dynamics from the simulations seems to be a key feature of dry friction subjected to noise and of general piecewise-smooth stochastic dynamics. Signatures of such intermittent dynamics have been found in the framework of the Boltzmann-Lorentz equation by investigating the so-called independent kick model [32, 33], in studies of dry friction subjected to Non-Gaussian noise in the high friction limit [23], and in an experiment of a rotating probe subjected to a granular gas [28]. Intermittent dynamics and a related splitting of the velocity distribution in a regular and a singular part can be clearly seen in numerical studies of the underlying transport equations [34]. Despite the importance of dry friction in engineering, only few explicit results on its interplay with noisy nonequilibrium environments are available in the literature. We think, that justifies a case study like eq.(3) to uncover potentially general features caused by discontinuities of the flow and noise with finite amplitude. Furthermore, the noise correlation time $\tau$ is used as a continuous control parameter in the analysis of our model. Such a parameter has not been available in the studies using the Boltzmann equation, where only limiting cases of frequent and rare collisions were investigated [27, 28, 32, 33].

III. STATIONARY DENSITY

Given the previous reasoning and the numerical findings we expect the stationary density to exhibit a singular component caused by particles sticking at $v = 0$. The corresponding stationary distribution is expected to consist of a Dirac $\delta$ component at vanishing velocities and $|\eta| < 1$, and a regular part describing moving particles with finite velocities. The analysis will be further hampered by the lack of detailed balance so that closed form analytic expressions are unlikely to be available.

A. Marginal distribution and unified coloured noise approximation

To make some analytical headway let us first have a look at the marginal velocity distribution $P_v =
\[ f_\infty P(v, \eta)dy \] for which perturbative treatments in terms of the correlation time are available. We are interested in possible changes compared to the white noise case \( \tau \neq 0 \) (see e.g. \[15\]). We apply the unified coloured noise approximation (UCNA), developed by Jung and Hänggi \[1\], to our regularized system eqs. (2) and (4). This method can be seen as a kind of interpolation scheme for systems with coloured noise, as this method shows, under certain conditions, exact results in the limit of vanishing correlation \( \tau \to 0 \) and high correlation \( \tau \to \infty \).

For the convenience of the reader, we recall the main steps of the derivation of the stationary probability density \( P_\tau(v) \). If we eliminate the variable \( \eta \) from eqs. (2) and (4) we obtain the second order equation

\[ \ddot{v}(t) + \dot{v}(t) \left( \sigma_x(v(t)) + \frac{1}{\tau} \right) = -\frac{\sigma_z(v(t))}{\tau} + \frac{1}{\tau} \xi(t). \]  

We introduce a new time scale \( \hat{t} = \tau^{-1/2} t \),

\[ \ddot{\hat{v}}(\hat{t}) + \dot{\hat{v}}(\hat{t}) \gamma(\hat{v}(\hat{t}), \tau) = -\sigma_z(\hat{v}(\hat{t})) + \tau^{-1/4} \xi(\hat{t}), \]  

where we have the damping factor

\[ \gamma(v, \tau) = \tau^{-1/2} + \tau^{1/2} \sigma'_x(v). \]  

This factor approaches infinity for both limits \( \tau \to 0 \) and \( \tau \to \infty \). Hence, the setup is suitable for an adiabatic elimination scheme in the limit of small correlation times. If we neglect the second order derivative we obtain a simpler multiplicative stochastic process

\[ \dot{\hat{v}}(\hat{t}) = -\frac{\sigma_z(\hat{v}(\hat{t}))}{\gamma(\hat{v}(\hat{t}), \tau)} + \frac{1}{\tau^{1/4} \gamma(\hat{v}(\hat{t}), \tau)} \xi(\hat{t}), \]  

with a corresponding Fokker-Planck equation in the Stratonovich sense

\[ \partial_t P_v = \partial_v \left( \frac{\sigma_z(v)}{\gamma(v, \tau)} + \frac{1}{2 \tau^{1/2} \gamma^2(v, \tau)} \right) P_v \]  

\[ + \frac{1}{2 \tau^{1/2} \gamma^2(v, \tau)} \partial_v^2 \left( \frac{P_v}{\gamma^2(v, \tau)} \right). \]  

Since the adiabatic approximation has reduced the problem to a one-dimensional Fokker Planck equation the stationary distribution can be computed by straightforward integration

\[ P_v(v) = \exp \left( -2 \int \sigma_z(v) dv - \tau \sigma'_z(v) + \ln \left( |1 + \tau \sigma'_z(v)| \right) \right). \]  

In the dry friction limit \( \varepsilon \to 0 \) the normalised stationary probability density reads

\[ P_v(v) = \frac{\exp \left( -2|v| - \tau \sigma'_z(v) \right) (1 + \tau \delta(v))}{\exp(-\tau) + \sqrt{\pi\tau \text{erf}(\sqrt{\tau})}}. \]  

Eq. (11) shows that the stationary probability density consists of two parts, a regular contribution for \( v \neq 0 \) and a singular part for \( v = 0 \). The delta contribution in the density reflects the fact that the particle sticks at \( v = 0 \) when the stochastic force is not large enough to move the particle. The regular part of the density describes the sliding motion of the particle for \( v \neq 0 \). By taking the white noise limit \( \tau \to 0 \) we arrive at the exact stationary probability density for dry friction with white noise (i.e. \[15\]). For high correlation times \( \tau \) the sliding contribution decreases and the density is mainly determined by the delta peak. Thus, by increasing \( \tau \) we can observe a gradual transition from sliding to sticking motion. The appearance of a delta peak in the expression for the stationary probability density has also been found in various theoretical studies \[21–23, 32–34\] and in experiments \[28\].

The accuracy of the perturbative approach can be confirmed by direct numerical simulations, see figure 4 for the comparison of the UCNA with direct numerical simulations. By taking at about 100 realisations of time traces of length \( T = 10^4 \), we observe good agreement for small correlation times. However, for values \( \tau > 0.1 \), deviations between numerics and analytics become visible.

In addition to the analysis of sliding events, eqs. (10) and (11) give as well an estimate for the singular part, in particular for the probability of sticking as a function of the noise correlation

\[ P_{\text{Stick}}(\tau) = \frac{\sqrt{\pi\tau \text{erf}(\sqrt{\tau})}}{\exp(-\tau) + \sqrt{\pi\tau \text{erf}(\sqrt{\tau})}}. \]  

To obtain this result one needs to integrate the regularized version, eq. (10), over a small interval containing \( v = 0 \) and then taking the limit \( \varepsilon \to 0 \). Figure 5 shows the comparison of the analytical approximation with the simulations and we observe a quite good agreement as the probability of sticking increases with increasing \( \tau \) and approaches the value 1 in the limit of high correlation times.

Overall, the analytic approximation seems to work rather well, especially for small \( \tau \). Deviations become visible when the noise correlation time increases (see figure 4 for the case \( \tau = 1.0 \)). To explain the deviations between the analytical approximation and the direct numerical simulations for the regular part/sliding events (figure 4), we need to take a look at the conditions of validity of the UCNA; this approximation gives proper results for the case \( \gamma(v, \tau) \gg 1 \). But for higher values of \( \tau \), this approximation fails as in our case the contribution caused by the dry friction vanishes in the limit \( \varepsilon \to 0 \), i.e., when considering the piecewise linear case. Nevertheless, this analytic approximation scheme provides very useful information of the underlying nonequilibrium dynamics of our model.

### B. Joint distribution and probability current

To get more insight into the dynamics of our model, we study the two-dimensional equations of motion (2).
FIG. 4: Regular part of the stationary density, i.e. distribution of the sliding events, obtained from numerical simulations (dashed lines) sampled as a histogram with resolution $\Delta v = 0.002$ and the analytical approximation, eq.(11) (solid line). Data have been displayed for different values of the correlation time $\tau = 0.001$ (a), $\tau = 0.1$ (b), $\tau = 1.0$ (c), cf. figures 1 - 3.

and (3) with the aim to understand properties of the stationary probability density $P(v, \eta)$.

To begin with we perform numerical simulations of the dynamics of eqs.(2) and (3) (see above for details of the numerical integration scheme). Density plots on a logarithmic scale of the full stationary distribution (regular and singular part) are shown in figure 6. For $\tau = 0.001$ the singular part hardly matters and results are almost indistinguishable from the white noise case within the resolution of our simulations. The regular density shows a Gaussian profile in the $\eta$ direction as well as exponential decay in the $v$ direction. By increasing $\tau$, the density changes significantly as the singular part becomes noticeable (cf. eq.(11) and figure 4). Furthermore, the regular part of the density becomes asymmetric as the two components in the half spaces $v > 0$ and $v < 0$ are shifted against each other.

For further analytical insight we try to formulate the corresponding Fokker-Planck system. Using the regularized version of the equations of motion, eqs.(2) and (4), the Fokker-Planck equation reads

$$\partial_t P = \partial_v (\sigma(v) - \eta) P + \partial_\eta \left( \frac{\eta}{\tau} + \frac{1}{2\tau^2} \partial_\eta \right) P.$$  \hspace{1cm} (13)

There is no obvious way to compute the stationary solution because detailed balance is violated. The marginal distribution for the noise amplitude is however easily computed as

$$P_\eta(\eta) = \sqrt{\frac{\tau}{\pi}} \exp(-\tau \eta^2)$$  \hspace{1cm} (14)

and does not depend on the regularisation. Hence eq.(14) applies as well in the dry friction limit $\varepsilon \to 0$, which does not come as a surprise (cf. eq.(2)). In the dry friction limit the expression

$$P(v, \eta) = \exp \left( -2|v| + 2\sigma_0(v)\eta - \tau \eta^2 \right)$$  \hspace{1cm} (15)

formally solves the stationary Fokker-Planck equation, see eq.(13) in the limit $\varepsilon \to 0$, as long as $v$ is nonzero. It differs from the regular part of the marginal (eq.(11)) by the sign of the mixed $(v, \eta)$ term. Certainly eq.(15) does not provide an analytic solution for the stationary density as eq.(15) does not obey the required matching conditions at $v = 0$. Nevertheless, if the impact of the stick-slip phenomenon at $v = 0$ remains localised then

FIG. 5: Probability of the sticking events as a function of the noise correlation time $\tau$. The dots correspond to numerical simulations of eqs.(2) and (3), the solid line corresponds to eq.(12).
FIG. 6: Logarithmic density plot of the stationary probability density, obtained from numerical simulations of eqs. (2) and (3), for different values of the correlation time: \( \tau = 0.001 \) (a), \( \tau = 0.1 \) (b), \( \tau = 1.0 \) (c). The density has been sampled with a resolution of \( \Delta v = 0.002 \) and 300 bins in \( \eta \)-direction. Slices of the density at \( v = 0 \) can be found in figure 9.

FIG. 7: Regular component of the stationary probability density at \( \tau = 0.1 \). Dependence on the noise amplitude for different fixed values of the velocity \( v \). Results of numerical simulations (dashed line) and analytic asymptotic expression (solid line), eq.(15). The normalisation of the analytics is fitted to the numerical data.

FIG. 8: Regular component of the stationary probability density at \( \tau = 0.1 \). Dependence on the velocity for different fixed values of the noise amplitude \( \eta \). Results of numerical simulations (dashed line) and analytic asymptotic expression (solid line), eq.(15). The normalisation of the analytics is fitted to the numerical data.

The singular part of the distribution, that means the dynamics of sticking particles is entirely governed by eq.(2), that means by the Fokker-Planck equation of the Ornstein-Uhlenbeck process. But natural boundary conditions do not apply as particles perform stick-slip transitions. For the singular part of the density at \( v = 0 \) we have already indicated that increasing the correlation time results in a considerable decrease of the probability of sliding particles. As a result the main contribution to the marginal distribution, eq.(14), will come from

eq(15) provides the asymptotic behaviour for large values of velocities. This assertion can be verified by looking into the numerical data. In figure 7 slices of the regular density taken at constant values of the velocity show deviations from the Gaussian profile close to the singular component, i.e., at low velocities. However, the Gaussian profile according to eq.(15) is restored when we increase the velocity, i.e., at regions in phase space further away from the sticking region. Deviations from the Gaussian profile or strictly speaking the asymmetry of the distribution in \( \eta \) direction can also be observed in figure 6 (bottom) for a high noise correlation \( \tau \). A similar feature is displayed by slices taken at constant noise level, see figure 8.
of two coupled Fokker-Planck equations, one governing the sticking and one governing the sliding motion, with appropriate matching conditions and source terms. It is however not obvious whether such a formulation for the regular and the singular component of the probability distribution would give more insight than direct numerical simulations of the associated Langevin equation, let alone providing a pathway for an analytic approach. Figure 12 indicates a non-monotonic behaviour of the current by varying the correlation time of the noise $\tau$. For low values of $\tau$, the current is very small, as we are close to the white noise limit. By increasing $\tau$ the current increases as well up to a value close to $\tau = 0.2$. Increasing $\tau$ further the current decreases and almost vanishes, see the results for $\tau = 3.0$ in figure 12. For higher values of the noise correlation the probability current decays rapidly outside of the interval $\eta \in (-1,1)$. In view of the particular structure of the stationary density this is hardly surprising, as the singular component of the density dominates for high correlation times, the dynamics is dominated by sticking particles, and only a small part of the probability density contributes to the sliding motion and finally to the probability current.
IV. DYNAMICAL PROPERTIES OF THE PIECEWISE LINEAR MODEL

Traditional correlation functions are a useful tool to study dynamical properties, in particular, within the context of linear response theories. From a theoretical perspective their analytical properties are related with the eigenvalue spectrum of the underlying equations of motion, e.g. with the spectrum of Fokker-Planck operators. Furthermore correlation functions are experimentally accessible and they allow to introduce the concept of correlation times. As a shortcoming correlation functions may not allow for the proper characterisation of intermittent behaviour, such as stick-slip transitions, which needs then to be addressed separately by a suitable statistical measure.

A. Power spectral density

To begin with, we want to investigate how the correlation time of the noise \( \tau \) influences the correlations in our system. To be slightly more precise we will discuss the \( \tau \)-dependence of the power spectral density of the velocity \( v \), and the corresponding linewidth. The latter provides insight into the structure of the eigenvalue spectrum of an underlying Fokker Planck operator governing the dynamics of the system. For the dry friction model with white noise (\( \tau = 0 \)), a spectral gap between the two first eigenvalues has been observed [15, 41]. In [16] a closed expression for the power spectral density of the velocity has been derived based on the Laplace transform of the propagator.

For noise with finite correlation time we mainly rely on numerical investigations since analytic expressions for the stationary probability density are unknown. We calculate the power spectral density of the variable \( v \) by averaging over 800 numerically generated time traces of length \( T = 10^4 \). We base our analysis on the autocorrelations of the velocity. Hence, the corresponding power spectral density predominantly probes properties of the sliding phase as velocities vanish in the sticking phase.

Figure 13 shows the numerical results of the normalised spectral densities for different values of \( \tau \). The normalised power spectral densities \( S_N(\omega) \) have a single central peak at \( \omega = 0 \) indicating an exponential decay of the corresponding autocorrelation function. For small values of \( \tau \), and in accordance with the white noise limit, \( S_N(\omega) \) is a Lorentzian with power law behaviour \( \omega^{-2} \) at an intermediate frequency range. Such decay changes when increasing the noise correlation time \( \tau \), resulting in a decay proportional to \( \omega^{-4} \) at medium frequencies. The corresponding analytic behaviour indicates a smooth autocorrelation function at time zero.

The complex valued singularities of the power spectral density are signatures of the the non-vanishing eigenvalue of an underlying Fokker Planck operator. For power spectral densities with a well defined central peak, the full
width at half maximum $\Delta \omega$ can be related to the correlation time of the system $t_{\text{corr}}$ via the Wiener-Khinchin theorem. Following results for linear stochastic processes we define here a correlation time by $t_{\text{corr}} = 1/\Delta \omega$. Using a fit function of the form $1/(1 + a\omega^2 + b\omega^4)$ for the power spectral densities $S_N(\omega)$ we evaluate the correlation time, see figure 14.

The correlation time $t_{\text{corr}}$ essentially coincides with the value of the white noise limit as long as $\tau < 0.1$. While there is no sharp transition, $t_{\text{corr}}$ significantly increases monotonically when the noise correlation time exceeds a "critical" value of $\tau = 0.1$. Hence, signatures of the stick-slip transition become dynamically visible above such a critical value. The transition-like feature is in accordance with the findings about the stationary density reported in the previous section, e.g. see figure 5.

B. Distribution of sticking and sliding periods

The time traces shown in figures 1 - 3 suggest a closer relation of the dynamics with intermittency phenomena. To probe directly the dynamical features of the stick-slip transition we look at the distribution of sticking and sliding times, i.e., the distribution of time intervals the particle spends in states $v = 0$ and $v \neq 0$.

We start our investigations with the analysis of the sticking time events. As the dynamics of sticking particles is mainly determined by the exit time problem of the Ornstein-Uhlenbeck process, see eq.(2), this problem can be treated by analytical means, see [42]. The Laplace transform of the exit time probability density for an Ornstein-Uhlenbeck process like eq.(2) with symmetric absorbing boundaries ($-a$ and $a$) and a fixed initial condition $|\eta_0| < a$ reads

$$f(s|\eta_0) = \frac{D_{-\tau^2}(-\sqrt{2\eta_0} \tau)}{D_{-\tau^2}(-\sqrt{2\eta_0} \tau) + D_{-\tau^2}(-\sqrt{2\eta_0} \tau)} \exp \left(\frac{s}{2}(\eta_0^2 - a)\right) = \exp \left(\frac{\sigma(a-1)}{2}\right) \frac{\Gamma\left(\frac{s}{2} + \frac{\sigma}{a}\right)}{\Gamma\left(\frac{s}{2} + \frac{\sigma}{a^2}\right)}.$$

(16)

where $D_\nu(x)$ is the parabolic cylinder function, $\Gamma(x)$ denotes Kummer’s confluent hypergeometric function and we have used some identities for these functions [43]. We set $a = 1$ as the regime, where particles are sticking, is the interval $(-1, 1)$, integrate over all possible initial conditions $\eta_0$ within this regime assuming a uniform distribution, to obtain

$$\tilde{f}(s) = \frac{1}{2} \int_{-1}^{1} f(s|\eta_0) d\eta_0 = \frac{1}{\sqrt{\frac{\sigma}{a^2}}} F_1\left(\frac{s}{2} + \frac{\sigma}{2a^2}\right).$$

(17)

As it is not possible to derive an analytic result for the inverse Laplace Transform of this expression, we use the Talbot method to calculate the exit time distribution numerically [44, 45]. The results for certain values of $\tau$ are shown in figures 15 - 17. One observes a localised peak in the distribution at $T = 0$, and for moderate to large times a simple exponential decay. For higher noise correlation times the exponential decay of the distribution becomes smaller. It becomes more likely for particles to stick at $v = 0$ which is in accordance with the results in the previous sections. Our numerical findings for the exit time distribution agree very well with the analytical estimate, i.e. the inverse Laplace transform of eq.(17). It works particularly well for large values of $\tau$ and fails to be valid if we approach the transition value $\tau = 0.1$ as stick-slip phenomena become noticeable around this value.

For the remainder of this section we focus on the statistics of the sliding events. Figures 18 and 19 show the
FIG. 15: Distribution of sticking time intervals, $f(T)$, on a semi-logarithmic scale for $\tau = 0.1$, obtained numerically ((blue) dashed line) and semi-analytically from the exit time problem for the Ornstein-Uhlenbeck process ((bronze) solid line) (the inverse Laplace Transform of eq.(17)).

FIG. 16: Distribution of sticking time intervals, $f(T)$, on a semi-logarithmic scale for $\tau = 0.5$, obtained numerically ((blue) dashed line) and semi-analytically from the exit time problem for the Ornstein-Uhlenbeck process ((bronze) solid line) (the inverse Laplace Transform of eq.(17)).

FIG. 17: Distribution of sticking time intervals, $f(T)$, on a semi-logarithmic scale for $\tau = 1.0$, obtained numerically ((blue) dashed line) and semi-analytically from the exit time problem for the Ornstein-Uhlenbeck process ((bronze) solid line) (the inverse Laplace Transform of eq.(17)).

FIG. 18: Distribution of sliding time intervals, $P(T)$, on a double-logarithmic scale for different values of the noise correlation time, obtained from numerical simulations.

V. CONCLUSION

We investigated a dry friction model subjected to coloured noise with the emphasis on nonequilibrium properties in a noisy piecewise-smooth dynamical system. By applying the unified coloured noise approximation (UCNA), we obtained an analytical expression of the stationary probability density for the velocity. The white noise limit $\tau \to 0$ reproduces the exact results, e.g., see [12]. As the noise correlation time increases, the stationary density develops a delta peak, as particles become more and more stuck at $v = 0$. By varying $\tau$ a transition form sliding to sticking dynamics could be observed.
A power law decay of the form $P(T) \propto T^{-3/2}$ occurs, indicating a relation with on-off intermittency. The black line shows a decay according to a power law $T^{-3/2}$.

FIG. 19: Distribution of sliding time intervals, $P(T)$, on a double-logarithmic scale for different values of the noise correlation time, obtained from numerical simulations. The black line shows a decay according to a power law $T^{-3/2}$.

By considering the equivalent two-dimensional system we were able to derive an asymptotic expression for the stationary density which is valid for large velocities and large noise amplitudes, far away from the stick-slip region. There was no obvious way to obtain a full analytic expression for the joint probability density $P(v, \eta)$ containing all the required matching conditions at $v = 0$ as detailed balance is violated. The latter has been clearly demonstrated by computing the non-vanishing stationary probability current.

Furthermore we studied the power spectral density numerically to obtain information about the velocity correlations, the corresponding correlation time, and the spectral gap of the underlying Fokker-Planck operator. Below a "critical value" one recovers the result for white noise limit. Increasing the noise correlation further, the full width at half maximum decreases, which is connected to a higher velocity correlation in the system. This decrease of the spectral width comes together with a change in shape of the power spectrum. For low values of $\tau$ the power spectral density is a Lorentzian while for values $\tau > 0.1$ the shape changes to a $\omega^{-4}$ decay for intermediate frequencies.

To complete our studies, we investigated the sliding and sticking time distribution as the time traces indicated a connection to intermittent dynamics. Results for the sticking time distribution were accessible via the exit time problem for an Ornstein-Uhlenbeck process with symmetric absorbing boundary conditions. For the sliding dynamics the related exit time problem with coloured noise and a constant drift is hard to tackle and we had to rely on simulations. For high noise correlation times a power law decay of the form $T^{-3/2}$ occurs, indicating a relation with on-off intermittency.

The references [27] and [28] provide probably the most comprehensive experimental and theoretical analysis of a device subjected to dry friction and a nonequilibrium granular heat bath. The corresponding theoretical considerations have been based on a Boltzmann equation approach. Results such as a ratchet effect induced by geometric asymmetries and the localisation of the velocity distribution are in accordance with measurements. Given the sophisticated nature of the underlying theoretical description, time correlations and power spectra are not accessible by analytic methods.

In our analysis we have addressed a simpler but related theoretical model, using coloured noise instead of a collision integral. There is no mathematical link between both models, and the Boltzmann equation and the dry friction model subjected to coloured noise are fundamentally different. Nevertheless we found various striking similarities. Time traces of the coloured noise model are surprisingly similar to those measured in experiments if the cases of rare and frequent collision limits are compared with large and small noise correlation time. In addition, both models produce densities with a singular component caused by the discontinuous drift, a feature which is common in a large class of piecewise-smooth stochastic models, see e.g. [22]. Such a property can be seen as a ubiquitous feature of stick slip phenomena which is not restricted to a particular theoretical or experimental realisation. Within the analysis of the dry friction model subjected to coloured noise we were able to derive an analytic expression for the weight of the singular component, which is otherwise hardly accessible (see e.g. as well [22]). The analysis of the coloured noise model is facilitated by a continuous control parameter, which has not been available in the aforementioned more realistic studies, where only the limiting cases of frequent and rare collisions could be addressed. We were able to identify a critical noise correlation time separating the white noise regime from models where noise correlations have a visible effect in the presence of discontinuous drifts. Our model allowed for a detailed analysis of nonequilibrium currents and power spectra. In particular the on-off intermittent characteristics is a promising result which is tempting to be checked experimentally. In addition to the setup used in [28] a realisation along the lines of [26] would allow to implement noise colour quantitatively and thus would provide a direct experimental comparison.

Apart from experimental confirmations the coloured noise model is remarkable as well from a plain theoretical perspective. In the extended $(v, \eta)$ phase space the model is described by a plain Fokker-Planck equation. Because of the particular structure of diffusion and discontinuous drift the two dimensional Gaussian white noise model develops a singular stationary density, proving that such a localisation phenomenon is by no means a feature that requires more complicated noise sources. Hence, features previously found in Boltzmann equations can be certainly captured by Fokker-Planck equations and simpler stochastic models, which may be amenable for an analytic treatment.
