Abstract. The integrable loop model with mixed boundary conditions based on the 1-boundary extended Temperley–Lieb algebra with loop weight 1 is considered. The corresponding $qKZ$ equation is introduced and its minimal degree solution described. As a result, the sum of the properly normalized components of the ground state in size $L$ is computed and shown to be equal to the number of vertically and horizontally symmetric alternating sign matrices of size $2L + 3$. A refined counting is also considered.

Keywords: loop models and polymers, solvable lattice models, topology and combinatorics

ArXiv ePrint: math-ph/0610067
1. Introduction

The present work is yet another chapter in the continuing story, inspired by the seminal papers [1, 2], of the interrelation between quantum integrability and combinatorics. It concerns the combinatorial interpretation of the ground state components of a quantum integrable one-dimensional (1D) Hamiltonian, or equivalently of the equilibrium distribution of a Markov process on planar connectivities of points (also called link patterns). We refer the reader to [3] for an overview of the relevant model, related to the Temperley–Lieb algebra. These ground state entries turn out to be integers which count classes of fully packed loop (FPL) configurations, better known in the mathematical literature as alternating sign matrices (ASMs). An important detail is that while the first articles [1, 2] considered models with periodic boundary conditions, subsequent work also studied also types of boundary conditions [4]–[7]. In particular in [3, 7] one can find a definition of the so-called mixed boundary conditions which will be used here. In the “loop model to ASM” dictionary, boundary conditions of the model translate into symmetry classes of ASMs.

Here we make use of the method of study developed in [8], and of its extension considered in [9], or more precisely of its reformulation in terms of the qKZ equation given in [10]. The essence of the method is to generalize the problem by introducing extra parameters (in a similar spirit as [11]), making the model inhomogeneous. We go further by replacing the eigenvector equation with a more general linear system, which we call a bit loosely the qKZ equation, which lets us vary an extra parameter q. The latter
generalization, although not strictly necessary for our purposes, is both conceptually satisfactory (allowing us to distinguish clearly what properties are dependent on or independent of \( q \)), and of some mathematical interest, in relation to representation theory [9] and algebraic geometry [10].

The plan of the article is as follows, In section 2 we give a brief description of the loop model with mixed boundary conditions and define our notations. In section 3 we define the \( q \)KZ equation and discuss the relevant solution. Section 4 contains the main application of this formalism: the computation of the sum rule of the model with mixed boundary conditions, as well as its refinement in the sense of [12]. Section 5 provides concluding comments.

2. Definition of the model

We provide here the minimum about the model with mixed boundary conditions introduced in [3] that is needed for our purposes, as well as other useful definitions. Let \( L \) be a fixed positive integer. Consider points on a line, numbered from 1 to \( L \), plus an extra point to the right of them. The space of states consists of right-extended link patterns (or right-extended matchings, in the language of [3]), that is, pairings of the points \( \{1, \ldots, L\} \) between themselves, allowing for an arbitrary number of unpaired points which are connected to the extra rightmost point, in such a way that all these connections can be drawn in the half-plane without crossings; see figure 1. There are \( \binom{L}{\lfloor L/2 \rfloor} \) such link patterns.

These link patterns form the canonical basis of a vector space, on which the one-boundary-extended Temperley–Lieb algebra [13, 14] acts. Its generators, \( e_1, \ldots, e_{L-1} \) and \( f \) send link patterns to other link patterns according to the standard graphical rule exemplified on figure 2. Each time a loop is formed, it must be erased and the state must be multiplied by a weight \( \tau \). On the other hand 'boundary loops' that go through the rightmost point produce no weight. The operators \( e_i \) and \( f \) satisfy the following relations:

\[
\begin{align*}
e_i^2 &= \tau e_i & e_i e_{i+1} e_i &= e_i & e_i e_j &= e_j e_i & |i - j| > 1 \\
f^2 &= f & e_{L-1} f e_{L-1} &= e_{L-1} & e_i f &= f e_i & i < L - 1.
\end{align*}
\] (2.1)
Loop model with mixed boundary conditions, $q$KZ equation and ASMs

Figure 2. Examples of action of Temperley–Lieb operators.

The term ‘mixed boundary conditions’ refers to the fact that link patterns are closed on the left, but open/extended on the right.

Set $\tau = -q - q^{-1}$. One can define the $R$-matrix

$$
\tilde{R}_i(z) = \frac{(q z - 1/q)I + (z - 1)e_i}{q - z/q}
$$

where $I$ is the identity operator, and the boundary $R$-matrix [15, 16]

$$
K(z) = \frac{(z - q^2/\zeta)(z - \zeta/q)I + (1 - q)(1 - z^2)f}{(q z - \zeta/q)(z - q/\zeta)}
$$

where $\zeta$ is an additional free parameter of the model (this expression can also be found in a different parameterization in the appendix of [7]).

These operators satisfy the unitarity equation:

$$
\tilde{R}_i(z)\tilde{R}_i(1/z) = I \quad K(z)K(1/z) = I
$$

the Yang–Baxter equation:

$$
\tilde{R}_i(z)\tilde{R}_{i+1}(z w)\tilde{R}_i(w) = \tilde{R}_{i+1}(w)\tilde{R}_i(z w)\tilde{R}_{i+1}(z)
$$

and the boundary Yang–Baxter (or reflection) equation:

$$
\tilde{R}_{L-1}(w/z)K(z)\tilde{R}_{L-1}(1/(wz))K(w) = K(w)\tilde{R}_{L-1}(1/(wz))K(z)\tilde{R}_{L-1}(w/z)
$$

doi:10.1088/1742-5468/2007/01/P01007
as well as the usual commutation relations $[\hat{R}_i(z), \hat{R}_j(z')] = 0$ for $|i - j| > 1$ and $[K(z), \hat{R}_i(z')]} = 0$ for $i < L - 1$.

An integrable model is usually defined by an infinite family of commuting transfer matrices. In the present context it is more relevant to consider scattering matrices $S_i$, $i = 1, \ldots, L - 1$, defined by

$$
S_i(z_1, \ldots, z_L) = \hat{R}_i(z_i/\zeta_{i+1})\hat{R}_{i+1}(z_i/\zeta_{i+2})\ldots\hat{R}_{L-1}(z_i/z_L)K(1/(z_i))
$$

$$
\times \hat{R}_{L-1}(z_L z_i)\ldots\hat{R}_i(z_{i+1} z_i)\hat{R}_{i-1}(z_{i-1} z_i)\ldots\hat{R}_1(z_1 z_i)
$$

(2.7)

where $s$ is yet another free parameter. Intuitively (as in the coordinate Bethe ansatz), $S_i$ corresponds to a ‘particle’ starting at location $i$ with spectral parameter $z_i$, moving to the left and crossing other particles with spectral parameters $z_j$, $j < i$, then reflecting at the left boundary by having its spectral parameter changed to $1/(z_i)$ (but with a trivial left boundary $R$-matrix), then going back to the right crossing all other particles, reflecting to the right with the matrix $K$ and having its spectral parameter inverted to $s z_i$, and finally moving back left to its original location by crossing particles with spectral parameters $z_j$, $j > i$.

It is a simple exercise to show, using the properties above, that these operators $S_i$ satisfy the following commutation relations:

$$
S_i(z_1, \ldots, s z_j, \ldots, z_L)S_j(z_1, \ldots, z_L) = S_j(z_1, \ldots, s z_i, \ldots, z_L)S_i(z_1, \ldots, z_L).
$$

(2.8)

In particular note that, when $s = 1$, the $S_i$ commute. This is the ‘physical’ situation that leads to the diagonalization problem for the $S_i$ (which will be investigated in detail in section 4). However, for the time being, we do want to keep $s$ free.

3. qKZ equation and its Laurent polynomial solution

3.1. The linear system

Consider the following set of equations for $\Psi_L$, a Laurent polynomial\(^1\) in the variables $z_1, \ldots, z_L$, with values in the vector space spanned by the right-extended link patterns of size $L$:

$$
\hat{R}_i(z_{i+1}/z_i)\Psi_L(z_1, \ldots, z_i, z_{i+1}, \ldots, z_L) = \Psi_L(z_1, \ldots, z_{i+1}, z_i, \ldots, z_L)
$$

(3.1a)

$$
K(z_L)\Psi_L(z_1, \ldots, z_L) = \Psi_L(z_1, \ldots, z_{L-1}, 1/z_L)
$$

(3.1b)

$$
\Psi_L(z_1, \ldots, z_L) = \Psi_L(1/(z_1), z_2, \ldots, z_L).
$$

(3.1c)

These equations mimic the definition of the model, corresponding to the behaviour of the ground state eigenvector $\Psi_L$ at the bulk, the right boundary and the left boundary respectively. In order to explain more precisely the connection with the previous section, one can compute $S_i\Psi_L$ for $\Psi_L$ a solution of equations (3.1). Going back to the definition (2.7) of the operators $S_i$, we apply successively equations (3.1) for $i, i + 1, \ldots, L - 1$, then equation (3.1b), then equations (3.1a) for $L - 1, \ldots, 1$, then equation (3.1c), then equations (3.1a) for $1, \ldots, i - 1$, and the end result is

$$
S_i(z_1, \ldots, z_L)\Psi_L(z_1, \ldots, z_L) = \Psi_L(z_1, \ldots, s z_i, \ldots, z_L).
$$

(3.2)

\(^1\) $\Psi_L$ can be made into a polynomial by multiplying it by $(z_1 \cdots z_L)^k$ for $k$ sufficiently large; this however makes equations (3.1b), (3.1c) look slightly less nice.
Thus, $\Psi_L$ is a vector that has very simple transformation properties under the action of the $S_i$. Equation (3.2) is in fact the $q$KZ equation (or more precisely, a variant of it since the original $q$KZ equation [17] is really the analogue for periodic boundary equations).

### 3.2. Laurent polynomial solution

We now claim the following.

If $s = q^3$, there exists a solution of equations (3.1), which is a centred Laurent polynomial of total degree width $2L(L - 1)/2$ and degree width in each variable $2(L - 1)$. The solution is unique up to normalization and can be constructed explicitly by starting from the base component (empty link pattern with no pairings, first in the examples of figure 1)

$$
\Psi_{L,0} = \prod_{1 \leq i < j \leq L} (q z_i z_j^{-1} - q^{-1})(q^{-1} z_j - q s^{-1} z_i^{-1})
$$

(3.3)

and applying equations (3.1a), (3.1b).

Similar statements have been made in various related models, and the strategy to prove them always follows the same general pattern. Here we shall simply explain why the equality $s = q^3$, as well as equation (3.3), necessarily holds, and how the latter fixes all other components.

First we rewrite equations (3.1a), (3.1b) by using the explicit forms (equations (2.2), (2.3)) of $\bar{R}$ and $K$. We obtain the following dichotomies:

(a1) If the link pattern $\pi$ contains the pairing $(i, i + 1)$, then noting that $e_i \pi = \tau \pi$ we can rewrite the component $\pi$ of equation (3.1a) as

$$
\sum_{\pi' \neq \pi; e_i \pi' = \pi} \Psi_{\pi'} = (q z_i - q^{-1} z_{i+1}) \partial_i \Psi_{\pi}
$$

(3.4)

where $\partial_i$ is the divided difference operator: $\partial_i F(z_i, z_{i+1}) = (F(z_{i+1}, z_i) - F(z_i, z_{i+1}))/ (z_{i+1} - z_i)$.

(a2) If $i$ and $i + 1$ are not paired in $\pi$, then $\Psi_{\pi}|_{z_{i+1}=q^2 z_i} = 0$ and $\Psi_{\pi}/(q z_i - q^{-1} z_{i+1})$ is symmetric in $z_i, z_{i+1}$.

(b1) If the point $L$ is unpaired in $\pi$, then noting that $f \pi = \pi$ we can rewrite the component $\pi$ of equation (3.1b) as

$$
\sum_{\pi' \neq \pi; f \pi' = \pi} \Psi_{\pi'} = \frac{1}{1 - q}(q - q^{-1} \zeta z_L^{-1})(z_L - q \zeta^{-1}) \tilde{\partial} \Psi_{\pi}
$$

(3.5)

where $\tilde{\partial} F(z_L) = (F(1/z_L) - F(z_L))/(1/z_L - z_L)$.

(b2) If the point $L$ is paired in $\pi$ (i.e. not connected to the rightmost point), then $\Psi_{\pi}$ has zeros at $z_L = q^{-2} \zeta$, $z_L = q \zeta^{-1}$, and $\Psi_{\pi}/((q - q^{-1} \zeta z_L^{-1})(z_L - q \zeta^{-1}))$ is unchanged by $z_L \rightarrow 1/z_L$.

Using these properties recursively, as well as the remaining equation (3.1c), one can determine all the ‘trivial’ factors in the components $\Psi_{\pi}$ depending on the properties of $\pi$:

- If no pairings occur between consecutive points $\{i, \ldots, j\}$, $\prod_{i \leq k < l \leq j} (q z_k - q^{-1} z_l) | \Psi_{\pi}$.
• If no pairings occur between consecutive points \(\{1, \ldots , f\}\), \(\prod_{1 \leq k < l \leq 2}(q^2 - s \ z_kz_l) \mid \Psi_\pi\).

• If \(L\) is unpaired and there are no pairings between the consecutive points \(\{i, \ldots , L-1\}\) and no unpaired points among them, \(\prod_{i \leq k < l \leq L}(1 - q^2z_kz_l) \mid \Psi_\pi\).

• If \(L\) is paired and there are no pairings in the interval \(\{i, \ldots , L\}\), \(\prod_{k=1}^{L-1}(q - q^{-1}\zeta^{-1}_k)(z_k - q^{-1}) \mid \Psi_\pi\).

The first and second properties imply that \(\Psi_{L,0}\) contains all the factors of equation (3.3), and since these exhaust the degree width of the claim, there can be no more (monomials included, since \(\Psi_{\pi_0}\) must be centred). Furthermore, it is clear that equations (3.4) and (3.5) allow us to build all other components starting from \(\Psi_{L,0}\), and can only preserve or lower the degree width. Finally, we shall show explicitly in the following examples how \(s = q^3\) is necessary for \(L = 2, L = 3\). Below we shall exhibit recurrence relations that allow us to produce \(\Psi_{L-2}\) from \(\Psi_L\); so the condition \(s = q^3\) must be true for any \(L\).

**Example.** In size \(L = 2\), there are only two components: the empty link pattern (numbered 0) and the link pattern that pairs 1 and 2 (numbered 1). Starting from

\[
\Psi_{2,0} = (q - q^{-1})(q^{-1}z_2 - qs^{-1}z_1^{-1})
\]

and noting that \(f\) sends 1 to 0, we compute

\[
\Psi_{2,1} = \frac{1}{1 - q^2}(q - q^{-1}\zeta^{-1}_2)(z_2 - q^{-1}z_1^{-1}) \partial \Psi_{2,0} = \frac{(q^4 - s)(qz_2 - \zeta/q)(z_2 - q/\zeta)}{(1 - q)q^2s z_2}.
\]

But we also have that \(e_1\) sends 0 to 1, so we can also compute

\[
0 = \Psi_{2,0} - (qz_1 - q^{-1}z_2)\partial_1 \Psi_{2,1} = \frac{(s - q^3)(q^2z_1 - z_2)(1 - q^2z_1z_2)}{(1 - q)q^3s z_1z_2}
\]

so we conclude that \(s = q^3\). Substituting this leads to

\[
\Psi_{2,0} = (z_1z_2^{-1} - q^{-2})(z_2 - q^{-1}z_1^{-1})
\]

\[
\Psi_{2,1} = -q^2(z_2 - q^{-1}\zeta^{-1})(z_2 - q^{-1}z_1^{-1})
\]

(note in particular the simplification in \(\Psi_{2,1}\) which becomes a Laurent polynomial in \(q\)).

In size \(L = 3\), we use the ordering of figure 1. Starting from \(\Psi_{3,0}\), we compute

\[
\Psi_{3,1} = (1/(1 - q))(q - q^{-1}\zeta^{-1}_3)(z_3 - q^{-1}z_1^{-1}) \partial \Psi_{3,0}
\]

and \(\Psi_{3,2} = -q\Psi_{3,0} + (qz_2 - q^{-1}z_3)\partial_2 \Psi_{3,1}\); skipping these intermediate steps, we note that since \(e_1^{-1}(2) = \{0, 1, 2\}\), we must have

\[
0 = \Psi_{3,0} + \Psi_{3,1} - (qz_1 - q^{-1}z_2)\partial_1 \Psi_{3,2} = (s - q^3)(q^2z_1 - z_2)(q^2z_1 - z_3)(q^2z_2 - z_3)R(z_1, z_2, z_3)
\]

where \(R\) is some irrelevant rational function. We conclude again that \(s = q^3\), and after simplification,

\[
\Psi_{3,0} = (z_1z_2^{-1} - q^{-2})(z_2 - q^{-1}z_1^{-1})(z_1z_3^{-1} - q^{-2})(z_3 - q^{-1}z_1^{-1})(z_2z_3^{-1} - q^{-2})(z_3 - q^{-1}z_2^{-1})
\]

\[
\Psi_{3,1} = (z_1z_2^{-1} - q^{-2})(z_2 - q^{-1}z_1^{-1})(q - q^{-1}\zeta^{-1}_3)(z_3 - q^{-1}z_1^{-1})
\]

\[
\times (-q^{-2}(z_1 + z_2) + q^{-3}(1 + q^{-1})z_3 - q^{-5}(z_1^{-1} + z_2^{-1})) + q^{-3}(1 + q^{-1}z_3^{-1})
\]

\[
\Psi_{3,2} = (z_2z_3^{-1} - q^{-2})(z_3 - q^{-2}z_2^{-1})(-q^{-1}z_1(z_2 + z_3) + q^{-2}(1 + q^{-1})z_2z_3
\]

\[
+ (q^{-3}\zeta + \zeta^{-1})(1 + q)z_1 - q^{-1}(z_2 + z_3)) + q^{-1}z_1(z_2^{-1} + z_3^{-1}) - q^{-4}(z_2 + z_3)z_1^{-1}z_2^{-1}
\]

\[
+ q^{-2}(1 + q^{-1})z_1^{-1}z_2^{-1} - q^{-1}(z_2^{-1} + z_3^{-1})
\]

\[
- (1 - q^{-1})q^{-1}(1 + q^{-1}) - q^{-4}z_1^{-1}(z_2^{-1} + z_3^{-1}) + q^{-2}(1 + q^{-1})z_2z_3^{-1})
\]
3.3. Recurrence relations

We derive here a recurrence relation with respect to the size $L$ satisfied by $\Psi_L$.

Consider $\Psi_L|_{z_i=q^2z_i}$ for $1 \leq i \leq L-1$. Using the results of previous section we know that only the components with a pairing $(i, i+1)$ are non-zero. Defining the operation $\phi_i$ that inserts into a link pattern $\pi$ of size $L-2$ the pairing $(i, i+1)$ (thus shifting the points $i, \ldots, L-2$ by 2), we claim that

$$
\Psi_{L,\phi_i(\pi)}(z_1, \ldots, z_L)|_{z_i=q^2z_i} = P_i(z_i; z_1, \ldots, z_{i-1}, z_{i+2}, \ldots, z_L)
\times \Psi_{L-2,\pi}(z_1, \ldots, z_{i-1}, z_{i+2}, \ldots, z_L)
$$

where $P_i$ is some Laurent polynomial of degree width $2(2L-3)$. The common factor $P_i$ can be found by factor exhaustion, up to a multiplicative constant; it is then simple to check that the left-hand side of equation (3.6) satisfies equations (3.1) at size $L-2$; one concludes by uniqueness of the solution of the prescribed degree that equation (3.6) holds. There remains a multiplicative constant that needs to be computed by taking an example.

Since we shall need in what follows only one recurrence relation, we do the computation of $P_i$ only for $i = L - 1$. In this case note that the empty link pattern of size $L-2$ is sent by $\phi_{L-1}$ to the link pattern with one pairing $(L-1, L)$. The latter is the only antecedent of the empty link pattern by $f$; thus its component is

$$
\Psi_{L,1} = \frac{1}{1-q}(q - q^{-1}z_L^{-1})(z_L - qz^{-1})\partial\Psi_{L,0}.
$$

Setting $z_L = q^2z_{L-1}$ we note that $\Psi_{L,0}$ vanishes, so we are left with only one term in $\partial\Psi_{L,0}$. Explicitly,

$$
\Psi_{L,1}|_{z_L=q^2z_{L-1}} = (q z_{L-1} - \zeta^{-1})(1 - q^{-4}\zeta z_{L-1}^{-1}) \prod_{1 \leq i < j \leq L-1} (z_i z_j^{-1} - q^2)(z_j - q^{-1}z_i^{-1})
\times \prod_{1 \leq i \leq L-2} (z_i z_{L-1}^{-1} - q)(z_{L-1} - q^{-4}z_i^{-1}).
$$

Dividing by $\Psi_{L-2,0}(z_1, \ldots, z_{L-2})$ we obtain

$$
P_{L-1}(z_{L-1}; z_1, \ldots, z_{L-2}) = (q z_{L-1} - \zeta^{-1})(1 - q^{-4}\zeta z_{L-1}^{-1})
\times \prod_{i=1}^{L-2} (z_i z_{L-1}^{-1} - q^2)(z_{L-1} - q^{-1}z_i^{-1})(z_i z_{L-1}^{-1} - q)(z_{L-1} - q^{-4}z_i^{-1}).
$$

All the factors can be expected on general grounds (zeros of $\Psi_L$), but our computation has produced the normalization constant.

4. Sum rule at the stochastic point

4.1. Stochastic point

A value of the parameters that is of special interest is $q = e^{\pm 2\pi i/3}$, that is, the weight of a loop is $\tau = 1$, and $s = q^3 = 1$. At this special value we notice that all operators $e_i$ and $f$ have the co-vector $v = (1, \ldots, 1)$ as left eigenvector, with eigenvalue 1: $ve_i = vf = v$. So do the operators $R_i$, $K$, as well as $S_i$. In stochastic processes, this is interpreted as the conservation of probability. Also, we note that the operators $S_i$ now commute according
to equation (2.8). It will therefore come as no surprise that equation (3.2) becomes the equation for their common (right) eigenvector with eigenvalue 1:

$$S_i(z_1, \ldots, z_L)\Psi_L(z_1, \ldots, z_L) = \Psi_L(z_1, \ldots, z_L).$$

(4.1)

We can now consider the limit $z_i \to 1$, in which all operators $S_i$ tend to the identity. Expanding to first order in any variable we note that $$(\partial/\partial z_j) S_i|_{z_k=1} = \alpha_{ij} H + \beta_{ij},$$

where $\alpha_{ij}$ and $\beta_{ij}$ are irrelevant constants, and $H$ is the Hamiltonian

$$H = \sum_{i=1}^{L-1} e_i + a f$$

(4.2)

in which we have set $a = 3/(\zeta + 1 + \zeta^{-1})$. $H$, being a sum of $L$ operators with the same left eigenvector, also possesses it, with eigenvalue $L - 1 + a$. Furthermore, if $a$ is real positive, it is easy to show that the matrix of $H$ in the canonical basis satisfies all properties of the Perron–Frobenius theorem, so $L - 1 + a$ is its largest eigenvalue, and its right eigenvector $\Psi_L$ defined by

$$H \Psi_L = (L - 1 + a) \Psi_L$$

(4.3)

is its Perron–Frobenius eigenvector. Of course $\Psi_L$ is up to a multiplicative constant $\Psi_L(1, \ldots, 1)$, but we choose its normalization in such a way that the component indexed by the empty link pattern is $\alpha L/2$.

Let us first discuss the case $\zeta = 1$, i.e. $a = 1$. All components turn out to be integers, and in [3] there is given a remarkable conjectural combinatorial interpretation of these numbers (à la Razumov–Stroganov conjecture [2]) which we explain now.

Define a fully packed loop configuration (FPL) to be a colouring of edges of a square lattice in two colours (say, occupied and empty) in such a way that external edges are alternately occupied and empty and that vertices have exactly two occupied adjacent edges and two empty adjacent edges. FPLs are known to be in bijection with alternating sign matrices (ASMs); see [3] for details. An FPL is called vertically (resp. horizontally) symmetric if it is symmetric with respect to the vertical (resp. horizontal) axis. Now we can state the conjecture: with our normalization each component $\Psi_\pi$ is an integer and counts the number of vertically and horizontally symmetric fully packed loop configurations of size $2L + 3$ with the connectivity of the corresponding link pattern $\pi$; see figure 3. As a corollary, the sum of components $v \cdot \Psi = \sum_\pi \Psi_\pi$ is equal to the total number of such configurations, or equivalently the number of vertically and horizontally symmetric alternating sign matrices (VHSASMs).

Let us now go back to a general value of $a$. A refinement of the previous conjecture, formulated in [12], states that the components provide an $a$-enumeration of the VHSFPLs, the power $a^{k/2}$ being related to the number $k$ of paths crossing the horizontal symmetry axis say, to the left of the centre, that go straight down two steps below this axis. Again, the sum of components becomes the $a$-enumeration of VHSASMs, where a weight $a$ is given to each pair of $-1$ s on the row below the horizontal symmetry axis and to the left of the centre.

Remark. At $a = 0$ the Hamiltonian becomes that of the model with closed boundary conditions (whose ground state eigenvector is related to the counting of VSASMs or even-sized analogues, see [4, 6, 3]), and one expects to recover the results of [18], which discusses
the inhomogeneous generalization. Keeping only the leading term of $\Psi$ as $\zeta \to 0$, one finds that only components with all points paired (except one if $L$ is odd) are non-zero, which is the sector preserved by the operators $e_i$, $i = 1, \ldots, L - 1$; and one could naively expect these limiting components to be exactly the polynomials introduced in [18], up to a common factor. Interestingly, this is not the case—if only because the polynomials in our case have higher degree and are coprime. A related crucial mismatch is that the $qKZ$ equations are different: that of the closed boundary conditions has a shift $s = q^6$, as opposed to $s = q^3$ here. Only at $q = e^{\pm 2\pi i/3}$, where the two $\Psi$ are ground state eigenvectors of the same transfer matrix or scattering matrices, is the identification correct. Indeed one can check that the components of $\Psi_L(\zeta \to 0)$ develop a common symmetric factor at $q = e^{\pm 2\pi i/3}$ (which is precisely the function $\chi_L(z_1, \ldots, z_L)$ to be defined below, cf equation (4.7)). A similar phenomenon of interrelation between $s = q^3$ and $s = q^6$ solutions of $qKZ$ was observed in [9,19] in the case of periodic boundary conditions.

**Example.** For $L = 4$, with the order of link patterns as on figure 1,

$$H = \begin{pmatrix} a & a & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 + a & a & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 & 1 + a & a \\ 0 & 1 & 0 & 2 & 1 & 2 \end{pmatrix}. \quad (4.4)$$

The sum of each column is $3 + a$, as it should be, and $\Psi_4$ is

$$\Psi_4 = (a^2, 3a, 2a(3 + a), 3, 3a(2 + a), 3(2 + a)). \quad (4.5)$$

The corresponding VHSASMs are drawn in [12]. At $a = 1$, $\Psi_4 = (1, 3, 8, 3, 9, 9)$, which sums to 33, the total number of VHSASMs of size 11. At $a = 0$, $\Psi_4 = 3(0, 0, 0, 1, 0, 2)$, which is the ground state eigenvector of the Hamiltonian with closed boundary conditions, normalized in such a way that the greatest common divisor (GCD) is the total number of VSASMs of size 5. Each component, once divided by this GCD, counts VSASMs of size 5 with prescribed connectivity.
4.2. Sum rule

We are particularly interested here in the ‘sum rule’ $Z_L(z_1, \ldots, z_L) := v \cdot \Psi_L(z_1, \ldots, z_L) = \sum_\pi \Psi_L, \pi(z_1, \ldots, z_L)$, where we have set $q = e^{\pm 2\pi i/3}$ but retained the spectral parameter dependence. $Z_L$ is a Laurent polynomial of degree width $2L(L - 1)/2$, $2(L - 1)$ in each variable. Applying $v$ on the left to equations (3.1) (remembering that $v$ is the left eigenvector of $\hat{R}_t$, $K$ with eigenvalue $1$), we find immediately that $Z_L$ is a symmetric function of its arguments, and that it is invariant by $z_i \to 1/z_i$. Next, we sum over $\pi$ in equation (3.6) and obtain

$$Z_L(z_1, \ldots, z_L)_{z_L=qz_{L-1}} = Z_{L-2}(z_1, \ldots, z_{L-2}) \times (1 - q z_{L-1} \zeta^{-1})(\zeta - q^2 z_{L-1}^{-1}) \prod_{i=1}^{L-2} (1 - q z_{L-1} z_i^{-1})^2(z_i - q^2 z_{L-1}^{-1})^2 \quad (4.6)$$

where we have made use of equation (3.7). The recurrence relation is started with $Z_0 = Z_1 = 1$. $Z_L$, being a Laurent polynomial of degree width $2(L - 1)$ in say $z_L$, is entirely fixed by its value at $2L - 1$ points. Equation (4.6) (using the symmetries of $Z_L$) provides us with the values of $Z_L$ at $z_L = q^{2L-1}$, which is more than enough. Therefore we only need to find the unique solution of this recurrence.

Introduce the following determinant ratio:

$$\chi_n(z_1, \ldots, z_n) = \frac{\det(z_i^{j+[j/2]-1} - z_i^{-j-[j/2]+1})_{1 \leq i \leq j \leq n}}{\det(z_i^j - z_i^{-j})_{1 \leq i \leq j \leq n}} \quad (4.7)$$

This function, a character of the symplectic group $Sp(2n)$, already appears in [18] and in [20], as we shall discuss in more detail. It is a symmetric Laurent polynomial of its arguments, invariant by $z_i \to 1/z_i$, of degree width $2[n/2(n/2 - 1)]$, and it satisfies the recurrence relation:

$$\chi_n(z_1, \ldots, z_n)_{z_n=qz_{n-1}} = \chi_{n-2}(z_1, \ldots, z_{n-2}) \prod_{i=1}^{n-2} (1 - q z_{n-1} z_i^{-1})(z_i - q^2 z_{n-1}^{-1}).$$

We then easily find that

$$Z_L(z_1, \ldots, z_L) = \chi_L(z_1, \ldots, z_L)\chi_{L+1}(z_1, \ldots, z_L, \zeta) \quad (4.8)$$

since it has the right degree and satisfies the recurrence.

**Example.** The first few sums:

$$Z_2 = z_1 + z_2 + \zeta + z_1^{-1} + z_2^{-1} + \zeta^{-1}$$

$$Z_3 = (z_1 + z_2 + z_3 + z_1^{-1} + z_2^{-1} + z_3^{-1})$$

$$\times \left( z_1 z_2 + z_1 z_3 + z_2 z_3 + z_1^{-1} z_2^{-1} + z_1^{-1} z_3^{-1} + z_2^{-1} z_3^{-1} \right)$$

$$+ (\zeta + \zeta^{-1})(z_1 + z_2 + z_3 + z_1^{-1} + z_2^{-1} + z_3^{-1})$$

$$+ z_1 z_2^{-1} + z_1 z_3^{-1} + z_2 z_3^{-1} + z_2 z_1^{-1} + z_3 z_1^{-1} + z_3 z_2^{-1} + 3).$$

Finally, we can take the homogeneous limit $z_i = 1$. In all that follows we redefine the normalization of $Z$ so that the smallest component is $\Psi_0 = a^{[L/2]}$ as before: $Z_L(a) = 3^{-L(L-1)/2} a^{[L/2]} Z_L(1, \ldots, 1)$. First we set $\zeta = 1 \ (a = 1)$ as well. The limit
where parameters go to 1 in equation (4.7) can be found, as always with these types of determinants, by setting \( z_i = \exp(\epsilon i) \) and letting \( \epsilon \) go to zero. This is strictly equivalent to using Weyl’s dimension formula for representations of \( Sp(2n) \). Define for future use \( h_i = i + \lceil i/2 \rceil - 1 \); then \( \chi_n(1, \ldots, 1) = \prod_{1 \leq i < j \leq n} ((h_j - h_i)/(j - i)) \prod_{1 \leq i \leq j \leq n} ((h_i + h_j)/(i + j)) \), so that
\[
\chi_n(1, \ldots, 1) 3^{-\lceil n/2(n/2-1) \rceil} = \prod_{1 \leq k \leq n-1 \atop 2 \mid n-1-k} \frac{|3k/2 + 1|(3k)!k!}{(2k + 1)!(2k)!} = 1, 1, 2, 3, 11, 26, 170, \ldots
\]
where we have divided by the appropriate power of 3 so that the resulting number has the following interpretation: it is, for \( n \) even, the number of cyclically symmetric transpose complement plane partitions on a \( n \times n \times n \) hexagon, and for \( n \) odd, the number of VSASMs of size \( n \). These numbers already appear as the sum of components in the case of closed boundary conditions \([6, 18]\).

Going back to \( Z_L \), the powers of 3 are cancelled by those coming from \( \Psi_{L,0}(1, \ldots, 1) = 3^L(L-1)/2 \), and we conclude that
\[
\sum_{\pi} \Psi_{\pi} = \prod_{k=1}^L \frac{|3k/2 + 1|(3k)!k!}{(2k + 1)!(2k)!} = 1, 2, 6, 33, 286, 4420, \ldots
\]
which is the formula for the number of VHSASMs of size \( 2L + 3 \) conjectured by Mills \([21]\) and proved by Okada \([20]\).

If we now reintroduce the \( \zeta \) dependence, we find an expression which, as already stated, is conjecturally the weighted sum of VSASMs where a weight \( a \) is given to each pair of \(-1\) s on the row below the horizontal symmetry axis to the left of the centre. In particular, in \([12]\) there was formulated a conjecture about \( \rho_L = (1/L)(d/da) \log Z_L \big|_{a=1} \) (which should be the average density of such \(-1\) s). Let us explain here how to compute this quantity.

One starts with the following identity related to \( GL(N) \) characters, valid for arbitrary integers \( h_i \):
\[
H_n(h_1, \ldots, h_N) = \prod_{i=1}^N \frac{h_i^n}{(h_j - h_i)^{n-1}} = \begin{cases} 0 & n < N - 1 \\ s_{n-N+1}(h_1, \ldots, h_N) & n \geq N - 1 \end{cases} (4.9)
\]
where \( s_n \) is the \( GL(N) \) Schur function associated to the Young diagram with one single row of length \( n \). This is proved by considering the generating function
\[
\sum_{n \geq 0} H_n t^n, \text{ using the fact that } H_0(h_1, \ldots, h_N, t^{-1}) = 0 \text{ and concluding with the identity } \sum_{n \geq 0} s_n(h_1, \ldots, h_N) t^n = \exp \sum_{n \geq 1} (\sum_i h_i^n) t^n / n. \]
Here we only need the case \( n = N \), which, according to Weyl’s dimension formula, corresponds to computing the first logarithmic derivative of a \( GL(N) \) character w.r.t. one parameter at the identity of the group, the result being \( \sum_i (h_i - i) \) which is nothing but the number of boxes of the Young diagram.

The corresponding ‘symplectic’ identity can essentially be obtained by replacing \( h_i \) with \( h_i^2 \). In the present case we wish to compute the second derivative with respect to \( \zeta \) of \( \log \chi_{L+1} \) (since the first vanishes). We deduce, with \( n = N = L + 1 \),
\[
\frac{d^2}{d\zeta^2} \log \chi_{L+1}(1, \ldots, 1, \zeta)|_{\zeta=1} = \frac{1}{(L + 1)(2L + 3)} \sum_{i=1}^{L+1} (h_i^2 - i^2) \quad (4.10)
\]
where we have specialized to \( h_i = i + \lceil i/2 \rceil - 1 \).
Performing the summation \( \sum_{i=1}^{L+1}(h_i^2 - i^2) = (L + 1)[(L/2)(5[(L + 1)/2] + 2)/3, \) and changing variables to \( a = 3/(\zeta + 1 + \zeta^{-1}) \), not forgetting the normalization \( \Psi_0 = a^{[(L/2)]} \), we obtain

\[
\frac{d}{da} \log Z_L|_{a=1} = [L/2] \left( 1 - \frac{5[(L + 1)/2] + 2}{2(2L + 3)} \right) \tag{4.11}
\]

which is equivalent to the expression given in [12].

5. Comments and conclusion

5.1. Relation to UUASM partition functions

In view of the conjecture of [3] and its refinement in [12], it is tempting to try to identify our sum rule with parameters \( Z_L(z_1, \ldots, z_L) \) with the partition function \( Z_{L}^{UU} \) of ASMs with two U-turn boundaries as introduced in [11]—that is the partition function of the six-vertex model with its usual weights depending on spectral parameters (and \( q = e^{\pm 2\pi i/3} \)) and certain special boundary conditions. The UUASMs are a slightly more general class of ASMs than VHSASMs, but they are the right objects to consider once spectral parameters are introduced; one can recover VHSASMs from UUASMs in the homogeneous limit, as will be discussed below. The comparison reveals subtle differences. UUASMs being defined in even size only, we must discuss the two parities separately.

- For even \( L \), \( Z_{L}^{UU} \) depends on \( L \) spectral parameters, just like ours (in the notations of [11] and [20], these are the square roots of our parameters \( z_i \)), plus two boundary parameters, called \( b \) and \( c \). In [20], the case \( b = c = q^{1/2} \) is treated and the partition function is found to be equal (up to irrelevant prefactors) to \( \chi_L(z_1, \ldots, z_L)\chi_{L+1}(z_1, \ldots, z_L, 1) \). This coincides with \( Z_L \) at \( \zeta = 1 \). It is in fact not too hard to check that if one sets \( b^2 = c^2 = q/\zeta \), one also obtains the dependence on \( \zeta \). The amusing observation is that, in the homogeneous limit \( z_i = 1 \), the condition \( b = c = q^{1/2} \) selects VHSASMs (of size \( 2L + 3 \)) among UUASMs; however, setting \( b^2 = c^2 = q/\zeta \) does not. This provides an apparently non-trivial equality of the weighted sum of UUASMs, where the weights are on the two U-turn boundaries (more precisely, each U-turn gets a weight of \( q - \zeta/q \) if it is the correct orientation of the arrow for a VHSASM of size \( 2L + 3, 1 - \zeta \) if it is the wrong orientation) and the weighted sum of VHSASMs where the weight \( a = 3/(\zeta + 1 + \zeta^{-1}) \) is on the row below the horizontal symmetry axis (for each pair of \(-1\) s to the left of the centre). As a check one can consider the case \( \zeta = q^2 \), which selects among UUASMs the VHSASMs one size less \( (2L + 1) \): the conjectured equality implies that the number of VHSASMs of size \( 2L + 3 \) with maximal power of \( a \) is equal to the number of VHSASMs of size \( 2L + 1 \), which can indeed be proven (in fact there is a bijective proof, which is left as an exercise).

- For odd \( L \), the situation is even more mysterious. \( Z_{L+1}^{UU} \) depends on \( L + 1 \) parameters, that is one more than in our model. In [20], the case \( b = c = q^{-1/2} \) (which, in the homogeneous limit, selects VHSASMs of size \( 2(L + 1) + 1 = 2L + 3 \)) is treated and the result is that \( Z_{L+1}^{UU}(z_1, \ldots, z_{L+1}) \propto \chi_{L+1}(z_1, \ldots, z_{L+1})\tilde{\chi}_{L+1}(z_1, \ldots, z_{L+1}) \), where \( \tilde{\chi} \) is a certain character of \( O(2(L + 1)) \) which satisfies \( \tilde{\chi}_{L+1}(z_1, \ldots, z_{L+1}) \propto \chi_L(z_1, \ldots, z_L) \). Thus \( Z_{L+1}^{UU} \) coincides with \( Z_L(\zeta = 1) \) on condition that one of its
spectral parameter is set to 1. It is unclear how to reintroduce $\zeta$ in the partition function of UUASMs, and inversely unclear how to incorporate the extra spectral parameter in our model.

5.2. Limit $q \to 1$ and geometry

The main focus of the present paper is on the special value $q = e^{\pm 2i\pi/3}$. However, the rational limit of the $q$KZ equation is also interesting. This corresponds to the limit $q \to 1$ (in [10] the limit is indifferently $q \to \pm 1$, but this is because the shift $s = q^h$; here $s = q^3 \to 1$ imposes $q \to 1$), that is, expanding to first non-trivial order in $\hbar$ as $q = e^{-\hbar/2}$, $z_i = e^{-\hbar w_i}$. In [10], it was found that solutions of the usual type $A$ (periodic boundary conditions) rational $q$KZ equation based on Hecke algebra quotients are related to the geometry (more precisely, equivariant cohomology) of certain $sl(L)$ orbital varieties. This idea was generalized in [22] to Temperley–Lieb models with other boundary conditions which are apparently much closer to the present work; the models were shown to be related to type $B$, $C$, $D$ orbital varieties. However, a key difference is that the geometric interpretation was ensured from the start by the fact that the $R$-matrix (both bulk and boundary) dependence in the spectral parameter had a specific form which matched the Hotta construction of the Joseph representation for orbital varieties. This resulted in slightly unusual variants of the Temperley–Lieb algebra. Here the strategy is different: using the standard 1-boundary extended Temperley–Lieb algebra, we are forced to use a certain boundary $R$-matrix whose geometric interpretation is not obvious. Note that the example of [23,24] shows that more exotic varieties/geometric constructions than orbital varieties/Hotta construction can appear in integrable models. We hope to come back to this question soon.

5.3. Positivity conjectures

In [19] it was observed that, in the case of periodic boundary conditions, the components of solutions of the $q$KZ equation in which the variables $z_i$ are set to 1 are polynomials with positive coefficients in the variable: (1) $\tau = -q - q^{-1}$ in the case $s = q^6$; and (2) $\tau' = q^{1/2} + q^{-1/2}$ in the case $s = q^3$. See also [25] for an interesting conjecture on the combinatorial interpretation of the sum of homogeneous components for arbitrary $q$ in the case $s = q^6$.

We list here the first few homogeneous $\Psi_L(z_i = \zeta = 1)$ in terms of $\tau'$ and after dividing by some common factors:

$\Psi_2 = (1, 1)$
$\Psi_3 = (1, 2, 2 + \tau'^2)$
$\Psi_4 = (1, 3, 2(3 + \tau'^2), 2 + \tau'^2, 5 + 3\tau'^2 + \tau'^4, 7 + 2\tau'^2)$.

Clearly the positivity still seems to hold. Note that the special values considered above, namely $q = e^{\pm 2i\pi/3}$ and $q = 1$, correspond to $\tau' = 1$ and $\tau' = 2$ respectively.

5.4. Other boundary conditions and prospects

Several times in this paper we have mentioned the similarities with the work [18]. This is no surprise because the present model is a generalization of the one considered in [18]: the
Hamiltonian of the model with mixed boundary conditions has an additional boundary term, and when the coefficient $a$ in front of it is set to zero one recovers the Hamiltonian of the model with closed boundary conditions. At the technical level, the main difference is that the boundary term implies that one must include a non-trivial boundary $R$-matrix satisfying the reflection equation. (Another difference, irrelevant at the ‘physical’ value $q = e^{\pm 2\pi i/3}$, is that the shift $s$ in the $qKZ$ equation turned out to be $q^3$ here, whereas it is $q^6$ in [18].)

Similarly, one could add another boundary term on the left, which results in the model with open boundary conditions [7], an even broader generalization. The analysis of the corresponding $qKZ$ equation is more involved, and is deferred to a future publication [26].

Acknowledgments

The author thanks L Cantini and J-B Zuber for comments, and P Di Francesco for pointing out [12]; and acknowledges the support of ANR program ‘GIMP’ ANR-05-BLAN-0029-01, European Marie Curie Research Training Networks ‘ENIGMA’ MRT-CT-2004-5652, ‘ENRAGE’ MRTN-CT-2004-005616 and of ESF program ‘MISGAM’.
