Abstract

Dark Matter may reside in sector without Standard Model (SM) gauge interactions. One way in which such a dark sector can still impact SM particles through non-gravitational interactions is via the “photon portal” in which a dark photon kinetically mixes with the ordinary SM photon. We study the implications of this setup for electron recoil events at TEXONO reactor and nuclear recoil events at the COHERENT experiment. We find that the recent COHERENT data rules out previously allowed regions of parameter space favored by the thermal relic hypothesis for the DM abundance. When mapped onto the DM-electron cross section, we find that COHERENT provides the leading direct constraints for DM masses $< 30$ MeV.

1. Introduction

The majority of the matter in our Universe is non-luminous and non-baryonic. To date, all evidence of this Dark Matter (DM) has been gravitational in nature. Many models of new physics predict DM candidates with additional interactions beyond gravity. Indeed, one of the most studied frameworks for explaining the DM abundance posits that some new non-gravitational interactions brought DM into thermal equilibrium in the early Universe through 2-to-2 annihilation processes. Eventually, Hubble expansion dilutes the DM density so much that the annihilation rate plummets and the abundance of DM “freezes-out.” The relic abundance of such thermal DM can easily be in line with observations for cross sections $(\sigma v)_{\text{ann}} \approx 6 \times 10^{-26}$ cm$^3$ s$^{-1}$, with a weak dependence on the mass of the DM. This is the classic hypothesis for DM as a Weakly Interacting Massive Particle (WIMP), which appears in many extensions of the SM. Being charged under electroweak interactions, however, the WIMP hypothesis leads to a number of predictions, which to date have only been tightly constrained.

A natural question is then: can the thermal relic hypothesis for DM survive beyond WIMPs? Indeed, a simple and theoretically motivated scenario is one in which DM and perhaps a whole...
array of new particles—a “hidden” or “dark” sector—shares no gauge interactions with the SM. In lieu of gauge interactions, the visible and hidden sectors may communicate through gauge invariant combinations of the fields in the two sectors. At the renormalizable level there are a surprisingly small number of options for such “portals”

$$\mathcal{L}_{\text{portal}} = \begin{cases} 
\epsilon F_{\mu\nu} F^{\mu\nu}_h & \text{(photon portal)} \\
|H|^2 |H^*_h| & \text{(Higgs portal)} \\
y(LH)N & \text{(neutrino portal)}
\end{cases}$$

(1.1)

where $F_{\mu\nu}$, $H_h$, and $N$ are respectively hidden sector field strengths, Higgses, and fermions. Typically the impact of each of these portals is separately treated, as each one leads to distinct search strategies.

In this paper we study the impact of the photon portal for light DM, in which the SM photon kinetically mixes with a $U(1)$ dark photon [1]. The implications of $\gamma - \gamma'$ kinetic mixing for DM has been widely studied [2, 3, 4, 5, 6, 7, 8]. At the phenomenological level, the photon portal gives rise to two main classes of probes: (1) direct detection signals from DM-proton or DM-electron scattering, and (2) the production of DM at accelerators and colliders. Given the strong direct detection constraints, we will focus on the sub-GeV regime for DM. Notice that the strength of the direct detection constraints for $>\text{GeV}$ DM masses is partly thanks to the coherent enhancement of the DM scattering on the nucleus.

In light of the recent discovery of coherent neutrino-nucleus scattering [9] by the COHERENT collaboration, we ask what the COHERENT data brings to bear on photon portal models of light DM. The possibility of producing and detecting light DM at coherent neutrino-nucleus experiments was was studied in [10]. We additionally study the ability of reactor neutrino experiments like TEXONO to constrain light DM from their electron recoil events. The mass reach of TEXONO extends to $\sim\text{MeV}$ masses, while COHERENT’s stopped pion source can access DM masses out to $\sim 65 \text{ MeV}$.

The remainder of this paper is organized as follows. In Sec. 2 we introduce the model of study with a kinetically mixed dark photon interacting with pairs of DM particles. In Sec. 3 we examine the sensitivity at TEXONO to dark photons produced via, $\gamma e^- \rightarrow V' e^-$, with $V'$ decaying to DM which then produces electronic recoil events. In Sec. 4 we look at the sensitivity at COHERENT to producing dark photons from neutral pion decay. At COHERENT the rate is dominated by the coherently enhanced nuclear recoil events. In Sec. 5 we show the derived COHERENT constraints on light DM in the context of the existing constraints on light DM finding that COHERENT excludes previously allowed thermal relic parameter space for $\lesssim 30 \text{ MeV}$ masses. Finally in Sec. 6 we conclude and comment on the potential for future limits on the model.

2. Light DM with Dark Photon Portal

We assume that the hidden sector $U(1)$ gauge group spontaneously breaks to give the dark photon $V'_\mu$ a mass. Then the relevant terms of the Lagrangian for DM interacting with a kinetically mixed
photon are

\[ \mathcal{L} = \mathcal{L}_X - \frac{1}{4} F'_{\mu\nu} F'_{\mu\nu} + \frac{1}{2} m_{V'}^2 V'_{\mu} V'_{\mu} - \epsilon F_{\mu\nu} F'_{\mu\nu} \]  

(2.1)

where the DM portion of the Lagrangian is

\[ \mathcal{L} = i \bar{X} \partial X - m_X \bar{X}X \]  

(2.2)

with \( D_\mu \equiv \partial_\mu - ig_X V'_\mu \) being the covariant derivative and \( g_X \) the gauge coupling. Strictly speaking we suppose that the dark photon kinetically mixes with the SM hypercharge field strength, which then induces mixing with both the \( Z \) boson and the SM photon after EW symmetry breaking. Throughout, we work directly with the low-energy photon-dark photon mixing parameter \( \epsilon \). Details on the procedures for diagonalization and canonical normalization are provided in [11].

In our analysis of TEXONO and COHERENT data we will always assume the mass hierarchy, \( m_{V'} > 2m_X \), such that the decay \( V' \to \bar{X}X \) is allowed. This assumption has ramifications for the thermal relic abundance of DM. First it means that pair annihilation, \( \bar{X}X \to V'V' \), is not permitted. Then the only annihilation mode for DM is \( \bar{X}X \to \bar{f}f \), where \( f \) is one of the EM charged particles of the SM.

The annihilation to EM charged states as predicted in this setup, leads to strong constraints from CMB data [12]. In fact current data is sufficiently strong to completely rule out \( s \)-wave annihilation for sub-GeV DM if its annihilation is dominated by EM-charged states. Two simple ways out of this conclusion, are to suppress CMB constraints either via assuming (1) \( p \)-wave annihilating DM, or (2) to introduce a particle/antiparticle asymmetry for DM. While the CMB constraints are completely negligible for \( p \)-wave annihilation they can still be relevant at limiting the particle-to-antiparticle ratio for asymmetric DM [13, 14, 15].

To obtain \( p \)-wave annihilation the photon portal model would have to invoke scalar DM, while the asymmetric DM case can accommodate either sermonic or scalar DM. For simplicity here we focus on fermionic DM, and expect the derived TEXONO and COHERENT bounds to be similar for scalar DM.

### 3. TEXONO’s Compton-Like Constraint

In this section, we build on the recent work in [16] which considered dark photon constraints from reactor neutrino experiments. Unlike [16] however, here we allow for the dark photon to decay to pairs of light DM which then subsequently scatter.

The fission process of a thermal reactor can produce a large quantity of prompt [16] \( \gamma \)-rays,

\[ \frac{dN_\gamma}{dE_\gamma} = 0.58 \times 10^{21} \left( \frac{P}{\text{GW}} \right) \exp \left( -\frac{E_\gamma}{0.91 \text{ MeV}} \right) \]  

(3.1)

With a typical thermal power of the order, \( P \sim \mathcal{O}(\text{GW}) \), around \( \mathcal{O}(10^{21}) \) of photons are produced at \( \mathcal{O}(\text{MeV}) \) energies. These \( \gamma \)'s can scatter with electrons in the reactor to produce dark photon \( V' \) in
a Compton-like process, $\gamma e^- \to V'e^-$. The dark photon flux is then a convolution of the prompt-$\gamma$
flux (3.1) and the differential cross section $d\sigma_{\gamma e^- \to V'e^-}/dE_{V'}$,

$$
\frac{dN_{V'}}{dE_{V'}} = \int \frac{dN_\gamma}{dE_\gamma} \frac{d\sigma_{\gamma e^- \to V'e^-}(E_\gamma)}{\sigma_{tot}dE_{V'}}dE_\gamma.
$$

(3.2)

Note that the differential cross section is normalized by the total cross section $\sigma_{tot}$ of Compton process
which dominates the interaction of prompt $\gamma$-rays inside the reactor. In Fig. 1(a) we show the $V'$
flux for 1 GW of thermal reactor power and $\gamma$-$V'$ mixing $\epsilon = 1$. The dark photon mass sets a natural
cut on its flux. From massless $V'$ to $m_{V'} = 1$ MeV, the flux drops by almost two orders. Note that
the cross section $\sigma_{\gamma e^- \to V'e^-}$ of Compton-like process is proportional to $\epsilon^2$.

![Fig. 1: The $V'$ flux (a), the DM $\chi$ flux (b), and the detected electron spectrum (c) from Compton-like scattering of
prompt $\gamma$ on electrons with 1 GW of thermal reactor power. For illustration we take $m_{V'} = 0.1, 0.5, 1, 2$ MeV, $m_\chi = 0$,
the $\gamma$-$V'$ mixing $\epsilon = 1$, and the dark sector gauge coupling $g' = 1$ in (a), (b), and (c). The subplot (d) shows the
sensitivity on $g_\chi^1$ for $m_{V'} > 2m_\chi$.](image)

The dark photon $V'$ then decays into a pair of DM particles if $m_{V'} > 2m_\chi$. Since the $V'$-$\chi$
coupling is much larger than the $V'$-$e$ coupling, the dark photon $V'$ mainly decays into a pair of $\chi$. The $\chi$
flux is then a further convolution,

$$
\frac{dN_{\chi}}{dE_{\chi}} = \int \frac{dN_{V'}}{dE_{V'}} \frac{d\Gamma_{V'\to\chi\chi}(E_{V'})}{\Gamma dE_{\chi}}dE_{V'}.
$$

(3.3)

Since the $V'$ decay is isotropic, the DM energy $E_{\chi}$ is evenly distributed within the kinematically
allowed range
\[ E_- \leq E_\chi \leq E_+ , \quad \text{where} \quad E_\pm = \frac{1}{2} E_{V'} \pm \frac{1}{2} \sqrt{E_{V'}^2 - m_{V'}^2 \sqrt{1 - \frac{4m_\chi^2}{m_{V'}^2}}} . \] (3.4)

Consequently, the flux cut is not present in the Fig. 1(b) of DM flux and the DM energy \( E_\chi \) can stretch to much lower scale, especially when \( m_\chi \ll m_{V'} \ll E_{V'} \). Since the \( V' \) decay width is normalized as \( d\Gamma/\Gamma \), the DM flux \( dN_\chi/dE_\chi \) is also proportional to \( \epsilon^2 \), the same as \( dN_{V'}/dE_{V'} \).

The scattered electron spectrum at the TEXONO experiment
\[
\frac{dN_e}{dE_e} = \frac{N_e T}{4\pi R^2} \int \frac{2dN_\chi d\sigma_{\chi e\rightarrow \chi\gamma}(E_\chi)}{dE_e} dE_\chi
\] (3.5)
do not drop that much when \( m_{V'} \) increases from 0 MeV to 1 MeV. This is because the TEXONO detection threshold is even higher. Only events with electron energy larger than 3 MeV can be recorded. As shown in Fig. 1(c), the detection electron spectrum is not significant affected for \( m_{V'} \lesssim 1 \) MeV. The decrease becomes visible when \( m_{V'} \) increases to 2 MeV. Note that the scattering cross section has \( \epsilon^2 g_\chi^2 \) dependence. In total, the scattered electron spectrum \( dN_e/dE_e \) is scaled by a factor of \( \epsilon^4 g_\chi^2 \). The factor of 2 associated with \( dN_\chi/dE_\chi \) comes from the fact that a single \( V' \) can produce two DM particles, \( \chi \) and \( \bar{\chi} \). Both of them can scatter with electron via \( t \)-channel \( V' \) mediation.

The prefactors in (3.5) takes into account the number of electrons \( N_e \), the integrated run time \( T \), and the dilution factor \( 1/4\pi R^2 \) of DM flux due to Gauss law. For the TEXONO experiment, 187 kg CsI(Tl) scintillating crystal detector is placed 28 meters from the core of a 2.9 GW thermal-power reactor. In the energy range 3 MeV \( \leq E_e \leq 8 \) MeV of recoiled electrons, the TEXONO has collected 414 \( \pm \) 80 \( \pm \) 61 events [17]. To make a rough estimation of the sensitivity, we assume the SM \( \bar{\nu}_e \) scattering with electron is consistent with the experiment central value and use the uncertainties to constrain the contribution from DM. We show the sensitivity the 95\% limit on the couplings \( \epsilon g_\chi^{1/2} \) in Fig. 1(d). The dependence of sensitivities on \( m_{V'} \) is minor for \( m_{V'} \lesssim 2 \) MeV and decreases much faster when \( m_{V'} \) goes beyond 2 MeV. Given \( m_{V'} \), the sensitivity is almost independent of the DM mass \( m_\chi \), especially for \( m_\chi < m_{V'}/4 \) when \( m_{V'} \lesssim 2 \) MeV and \( m_\chi < 0.4 \times m_{V'} \) when \( m_{V'} > 2 \) MeV. It is interesting to see that the TEXONO measurement of electron recoil can already constrain the dark coupling to \( \epsilon g_\chi \) as small as \( \mathcal{O}(10^{-5}) \) for \( m_{V'} \approx 1 \) MeV.

4. COHERENT Constraint

The COHERENT experiment recently measured for the first time the neutrino-nucleus coherent scattering [9] with neutrinos produced by a source of stopped charged pions. It utilizes \( 1.76 \times 10^{21} \) of \( \sim 1 \) GeV protons striking a mercury target. As a byproduct, the same proton beam can also produce neutral pions which mainly decays into a pair of photons. We use the analytic expressions in [18] to estimate the spectrum of neutral pions, \( dN_{\pi^0}/dE_{\pi^0} \).

With \( \gamma-V' \) mixing, neutral pions have a non-negligible probability of decay into the dark photon, \( \pi^0 \rightarrow \gamma V' \). The dark photon spectrum is then a convolution of the \( \pi^0 \) spectrum and the differential
branching ratio of the $\pi^0 \to \gamma V'$ decay,

$$\frac{dN_{V'}}{dE_{V'}} = \int \frac{dN_{\pi^0}}{dE_{\pi^0}} \frac{d\Gamma_{\pi^0 \to \gamma V'}(E_{\pi^0})}{\Gamma_{\pi^0} dE_{V'}} dE_{\pi^0}.$$  \hspace{1cm} (4.1)

In Fig. 2(a) we show the normalized $V'$ spectrum with different mediator masses, $m_{V'} = 1, 10, 50, 100$ MeV. Although there is a kinematic cut $E_{V'} > m_{V'}$, the spectrum goes to zero smoothly. From $m_{V'} = 1$ MeV to $m_{V'} = 100$ MeV, the spectrum peak drops by a factor of $5 \sim 6$. The dark photon $V'$ further decays into a pair of dark matter particles. We show the normalized DM spectrum in Fig. 2(b).

Here the DM $\chi$ from $V'$ decay scatters with nuclei via $V'$ mediation, in a manner analogous to the scattering with electrons in the TEXONO experiment considered in Sec. 3. In the coherent region, the cross section,

$$\frac{d\sigma}{dE_r} = \frac{Q_{eff}^2(q^2) F^2(q^2)}{8\pi (E_r^2 - m^2_\chi)} \left[ 2(g_V^2 + g_A^2) M_N E_r^2 \left( 1 - \frac{E_r}{E_\chi} - \frac{M_N E_r}{2E_\chi^2} \right) - g_A^2 m^2_\chi (E_r + 2M_N) \right],$$  \hspace{1cm} (4.2)

can feel the effective charge of the nucleus collectively, $Q_{eff} = \epsilon Z e/(q^2 - m^2_{V'}).$ Consequently, the cross section is modulated by $Z^2$ instead of $Z$ and hence is significantly enhanced. The recoil energy $E_r \equiv q^2/2M_N$ is proportional to the momentum transfer $q^2$, suppressed by the nucleus mass $M_N$, 

Fig. 2: The normalization fluxes for $\chi$ (a) from $\pi^0$ decay at the COHERENT experiment. On the detection side, (b) shows the recoil energy spectrum in 308 live-days of data collection with 14.6 kg of CsI[Na] while (c) and (d) shows the corresponding 95% sensitivity on the DM coupling $\epsilon g_{V'}^{1/2}$. In the first two subplots, the DM mass is simply set to zero, $m_\chi = 0$, and $\epsilon = 1$ as well as $g' = 1$. 

and constrained within the range

\[
0 \leq E_r \leq \frac{2M_N(E^2_r - m^2_{\chi})}{m^2_{\chi} + M^2_N + 2M_N E_r} \approx \frac{2E^2_r - m^2_{\chi}}{M_N}.
\]

(4.3)

Since the nucleus mass \( M_N \sim \mathcal{O}(100\text{GeV}) \) is much larger than the DM mass \( m_{\chi} \sim \mathcal{O}(100\text{MeV}) \), the recoil energy is significantly suppressed to keV energies as shown in Fig. 2(c). Note that the COHERENT experiment uses 14.6 kg CsI target for detection, such that the contribution of coherent scattering on both Cs and I must be included.

The recoil energy spectrum can be directly confronted with the COHERENT data to give constraints on the DM couplings. On top of the SM neutrino background that is shown as the shaded histogram in Fig.3 of [9] we add the DM contribution to fit the COHERENT data points in the same figure. For convenience, we adopt the analytic \( \chi^2 \) fit technique detailed in [19] to estimate the sensitivity on DM coupling \( \epsilon g_{\chi}^{1/2} \). The \( \chi^2 \) function is defined as

\[
\chi^2 \equiv \sum_i \left( \frac{f_{SM} N^i_{SM} + f_{\chi} N^i_{\chi} - D_i}{\sigma_i} \right)^2,
\]

(4.4)

where \( f_{SM} \) is the normalization for the SM contribution from neutrino coherent scattering with the nucleus and \( f_{\chi} \) is the counterpart for DM-nucleus coherent scattering. If the SM is complete description, the normalization factors reduce to \( f_{SM} = 1 \) and \( f_{\chi} = 0 \). These are the two parameters to be adjusted in the \( \chi^2 \) fit. On the other hand, \( N^i_{SM} \) is the SM event number inside the \( i \)-th bin while the DM counterpart \( N^i_{\chi}(m_{\nu'}, m_{\chi}, \epsilon, g_{\chi}) \) is a function of the DM sector parameters. During a single fit, we fix the four DM sector parameters and adjust the two normalizations \( f_{SM} \) and \( f_{\chi} \). The marginalized uncertainty \( \Delta f_{\chi} \) can then be expressed in terms of sensitivity on \( \epsilon g_{\chi}^{1/2} \),

\[
\epsilon g_{\chi}^{1/2} \leq (\Delta f_{\chi})^{1/2}.
\]

(4.5)

In Fig. 2(d) we show the 95% sensitivity constraint on the DM coupling \( \epsilon g_{\chi}^{1/2} \). Interestingly, the result is almost independent of the DM mass \( m_{\chi} \) for a given dark photon mass \( m_{\nu'} \). For \( m_{\nu'} \lesssim 40 \text{MeV} \), the curves are nearly vertical. In other words, the sensitivity does not change much when varying \( m_{\chi}/m_{\nu'} \) or equivalently \( m_{\chi} \). Only for mediators masses \( m_{\nu'} \gtrsim 50 \text{MeV} \), does the sensitivity show some slight dependence on \( m_{\chi} \).

5. Comparison with other constraints: COHERENT at the Direct Detection Frontier

A number of other earlier experiments also constrain the same parameter space for photon portal DM. Some of these include LSND data, BaBar, and XENON10 data.

For illustration we map these bounds into the \( \tilde{\sigma}_e-m_X \) plane where \( \tilde{\sigma}_e \) represents the DM-electron cross section. This cross section is

\[
\tilde{\sigma}_e = \begin{cases} 
16\pi\alpha\alpha_X e^2 \mu^2_{eX}/m^4_{\nu'} & (m_{\nu'} \gg m_X) \\
16\pi\alpha\alpha_X e^2 \mu^2_{eX}/(m_e\alpha)^4 & (m_{\nu'} \ll m_X), 
\end{cases}
\]

(5.1)
Fig. 3: The COHERENT bounds derived in this work in the context of other bounds on DM interacting with a kinetically mixed dark photon. See Sec. 5 for a description of these additional bounds. Additional bounds can be found in [29]. The left and right panels take $m_{V'} = 3 m_X$ and $m_{V'} = 10 m_X$ respectively.

where in the latter case the atomic electron momentum dominates the momentum exchange, and $\mu_{eX}$ is the electron-DM reduced mass. In the mass range of interest, we are always in the regime where $\sigma_{ee} \propto m_X^{-4}$.

To compare with existing constraints, we map our bounds on the dark photon couplings to the $\sigma_{ee}$ plane in Fig. 3. Notice that the $\sigma_{ee} \propto g_X^2 \epsilon^2$, whereas COHERENT bounds the combination $\epsilon^2 g_X$. Therefore to draw the COHERENT bound in in the $\sigma_{ee}$ plane one must make an explicit choice for $g_X$. We take $g_X = 1$ in Fig. 3 in order to show conservative constraints. The other displayed constraints include the direct XENON10 bounds [20], BaBar’s $e^+e^- \rightarrow \gamma + \text{invisible}$ search [21, 22, 23, 24], and $N_{\text{eff}}$ bounds on the CMB and BBN era radiation density [25]. In addition the experiment NA64 searches for invisible decays of the dark photon and recently established updated limits [26]. We note as well that the recent updates to low-mass DM-nuclear scattering are quite strong and can also be mapped into the above plane [27, 28].

As we can see from Fig. 3, the COHERENT data is already sufficiently strong to probe thermal relic DM at a level not probed by other experiemnts. In particular for $m_{V'} = 3 m_X$, COHERENT excludes thermal relic cross sections for $m_X \lesssim 30$ MeV. Since the BaBar constraint constrains thermal relics to have masses, $m_X < 800$ MeV, there is remains a window of allowed masses $30 \lesssim m_X \lesssim 800$ MeV for this class of models to successfully account for the relic abundance via the standard freeze-out mechanism. Future COHERENT data as well as future direct detection limits [29, 30, 31, 32, 33, 34, 35, 36] on electron scattering may probe the remaining range of allowed masses.
6. Conclusion

In this paper we studied the implications of recent data from both TEXONO and COHERENT for the photon portal interaction of light DM. In TEXONO’s case the dark photon is produced in a Compton-like process, $\gamma e^- \rightarrow V' e^-$, and $V'$ subsequently decays to pairs of DM particles which then scatter off the electrons. For COHERENT the neutral pion decays provide the dark photon production, $\pi^0 \rightarrow \gamma + V'$, and the coherent enhanced nuclear scattering provides the main detection method.

In the future we expect COHERENT’s sensitivity to improve considerably. In addition to the raw exposure, the collaboration plans to use additional nuclear targets beyond the CsI used in the present dataset. For example, if anomalous DM induced events were present in future data, the correlation with the predicted $\sim Z^2$ coherent enhancement with different nuclei would provide an additional handle for discriminating the presence of DM.

We also note that the reactor based coherent neutrino scattering experiment MINER [37] will soon take data as well. Although the reactor power at MINER will be orders of magnitude below TEXONO’s, the significant reduction in energy threshold expected by MINER may open up new parameter space for them, though only at sub-MeV DM masses.
