Abstract

The Wigner–Weisskopf-type model describing the energy transfer between two centres mediated by a continuum of energy levels is studied. This work is motivated by the recent interest in transport phenomena at nanoscale in biology and quantum engineering. The analytical estimation for the energy transfer efficiency is derived in the weak coupling regime and the conditions for the almost perfect transfer are discussed. The embedding of the standard tight-binding model into the Wigner–Weisskopf one which includes the environmental noise is presented.

1. Introduction

The almost perfect energy transfer (APET) in biologically relevant molecular systems attracted the attention of physicists in recent years [1]. Similar phenomena should also be observed in the engineered systems relevant for information processing like arrays of quantum dots or Josephson junctions [2]. Most of the theoretical analysis is performed using a tight-binding Hamiltonian for an interacting N-body system in the single excitation regime. The influence of environment is usually modelled by Markovian master equations with phenomenological decay parameters. The numerical computations show the interplay between quantum propagation, quantum localization, decoherence and dissipation [3–5]. The aim of this paper is to present a simple, essentially exactly solvable model which describes a generic class of such phenomena and allows us to derive analytical bounds on the efficiency of energy transfer processes. The motivation for the applied formalism comes from the particular model of two identical atoms placed in the focuses of two parabolic mirrors separated by a distance \( \ell \), see figure 1. We assume that the dipole moments of both atoms are parallel to the symmetry axis of the system. If initially the first atom is excited and the second is in the ground state, we expect that roughly after time \( t \approx \ell/c + O(\tau) \), where \( \tau \) is a mean life-time of the excited state, the energy quantum carried by a photon is almost perfectly transferred to the second atom. Obviously APET demands fine-tuning conditions: the atoms should be identical, placed exactly at the focuses of perfectly aligned mirrors and the dipoles should be parallel to the symmetry axis.

The simple description of such a system can be given in terms of the Wigner–Weisskopf (W–W) Hamiltonian (compare the case of a single mirror and a single atom [7]). The conditions which allow for APET are encoded entirely in the structure of the Hamiltonian which is determined by the details of the model. Treating the W–W model as a generic one of a large class of energy transfer phenomena between two localized centres, one can try to find a general bound for the efficiency of such a process and determine the sufficient conditions for APET.

2. Wigner–Weisskopf model

In order to introduce a 2-state W–W model, we consider a quantum system of two 2-level atoms interacting with an electromagnetic field which can be described by the standard Hamiltonian in the rotating wave approximation:

\[
\begin{align*}
H &= \frac{\omega_1}{2} \sigma_1^z + \frac{\omega_2}{2} \sigma_2^z + \int d^3k \omega(k) a^\dagger(k)a(k) \\
&+ \sigma_1^+a(g_1) + \sigma_1^- a^\dagger(g_1) + \sigma_2^+a(g_2) + \sigma_2^- a^\dagger(g_2).
\end{align*}
\]  

(1)

The operators \( a(g) \) and \( a^\dagger(g) \) are smeared annihilation and creation operators, respectively, for the electromagnetic field.
given by \[ a^j(\mathbf{k}) = \int d^3 k \, g(\mathbf{k}) a^j(\mathbf{k}), \quad g_j(\mathbf{k}), \quad j = 1, 2, \]
are the suitable form factors, and the quantum fields satisfy \( a^j(\mathbf{k}), a^j(\mathbf{k}') \) -(we omit for simplicity the polarization degrees of freedom). The standard 2 \( \times \) 2 Pauli matrices \( \sigma_{1,2} \) refer to 2-level atoms. In the case of identical atoms with relative position described by the vector \( \mathbf{r} \), the form factors differ by the relative phase \( L(\mathbf{k}) = \mathbf{k} \cdot \mathbf{r} \):

\[
g_{2} (\mathbf{k}) = e^{-iL(\mathbf{k})} g_{1} (\mathbf{k}). \tag{2}
\]

The crucial property of the Hamiltonian (1) is the commutation \( \{\hat{H}, a^j(\mathbf{k})\} = 0 \), the subspace corresponding to the eigenvalue 1 of \( N_{ex} \), which can be called single-exciton Hilbert space, is invariant under the evolution. It possesses a direct orthogonal sum structure, i.e., it is spanned by the following vectors:

1. \( |1\rangle \equiv |↑⟩ \otimes |\text{vac}⟩ \otimes |↓⟩ \);
2. \( |2\rangle \equiv |↓⟩ \otimes |\text{vac}⟩ \otimes |↑⟩ \);
3. \( |f\rangle \equiv |j⟩ \otimes |\text{vac}⟩ \otimes |j⟩ \)

for any wave packet \( f \).

Here, \( |j⟩ \) denotes the excited and ground states of the \( j \)-th atom, respectively, and \( |\text{vac}⟩ \) is the vacuum state of an electromagnetic field. This mathematical construction, which has been used frequently in quantum optics [6], will be called the 2-state W–W model.

The 2-state W–W model is suitable for the following generic physical situation. We restrict ourselves to physical systems which can be described in terms of the single-exciton Hilbert space \( \mathcal{H}_{ex} \). In this Hilbert space, we choose two orthogonal vectors \(|1\rangle, |2\rangle \) which are determined by the initial state preparation and the measurement procedures. Namely, the initial state (‘donor’) of the system at time \( t_0 = 0 \) is denoted by \(|1\rangle \), while the measurement at time \( t > 0 \) after preparation is a von Neumann projection on the state \(|2\rangle \) (‘acceptor’).

The Hilbert space of the model system is decomposed into a direct sum (compare with (5))

\[
\mathcal{H}_{ex} = \mathbb{C} \oplus L^2(\Omega) \oplus \mathbb{C} \tag{6}
\]

where the one-dimensional subspaces \( \mathbb{C} \) are generated by the states \(|1\rangle, |2\rangle \) and the Hilbert space \( L^2(\Omega) \) is their orthogonal supplement. For convenience, we represent this Hilbert space as the space of wave packets \( f(k), g(k), k \in \Omega \), denoted by \(|f⟩, |g⟩ \) with the scalar product

\[
⟨f|g⟩ = \int_{\Omega} f(k)\bar{g}(k) \, dk. \tag{7}
\]

One should stress that the above notation is used for convenience only. One can always replace the continuous variable \( k \) by a joint set of continuous variables \( \omega \) and discrete quantum numbers \( m \) such that \(|k⟩⟩\) is replaced by \(|\omega, m⟩⟩\) and

\[
⟨\omega, m |\omega', m'⟩⟩ = δ(\omega - \omega')δ_{mm'}, \quad \text{and} \quad \int_{\Omega} dk \leftrightarrow \sum_{m} \int d\omega.
\tag{8}
\]

The 2-state W–W Hamiltonian, which can be seen as the restriction of (1) to the single-exciton space, reads

\[
H = H_0 + V,
\]

where

\[
H_0 = \omega_1 |1⟩⟨1| + \omega_2 |2⟩⟨2| + \int d\omega \, (\omega |k⟩⟨k| |k⟩⟨k|), \tag{9}
\]

\[
V = (|1⟩⟨g_1| |1⟩⟨g_1|) + (|2⟩⟨g_2| |2⟩⟨g_2|).
\]

where \( g_{1,2} \in L^2(\Omega) \). All details of the model are hidden in the form of form factors \( g_{1,2} \) and the spectral resolution of the part of the Hamiltonian denoted here by \( \int_{\Omega} dk \, \omega(k) |k⟩⟨k| \).

Remarks. The presented model should be treated as an open quantum system where the system consists of a donor and an acceptor and the continuous modes form a reservoir. Note that strictly speaking for the 2-atom model presented in the introduction, the cavity formed by the mirrors is finite and hence the modes are discrete. Therefore the W–W Hamiltonian applies to the case of a large-enough cavity such that the Heisenberg time \( t_H = 1/\delta \omega \) (\( \delta \omega \) —characteristic energy level splitting of modes) is much longer than any relevant time scale. Alternatively, the continuous spectrum can be used if the modes themselves are unstable, due to environmental effects, and have finite life-times comparable to \( t_H \).

3. Efficiency of energy transfer

The system begins its evolution in the excited state \(|1⟩⟩\) and after time \( t \) can be found in the state \(|2⟩⟩\) with the probability

\[
\mathcal{P}_{12}(t) = |A_{12}(t)|^2, \quad A_{12}(t) = (2) e^{-iHt}|1⟩⟩. \tag{10}
\]

The APET holds if \( t_H \gg t \), and for a certain time \( t_0 \) the transfer probability \( \mathcal{P}_{12}(t_0) \approx 1 \). To find the sufficient conditions for APET in terms of the Hamiltonian (9), note that the (complex) probability amplitude \( A_{12}(t) \) is a scalar product of two states, \( e^{-iHt}/2|1⟩⟩ \) and \( e^{iHt}/2|2⟩⟩ \), which evolve forward and backward in time, respectively. For \( t \gg \tau \), where \( \tau \) is the life-time of the excited states, one expects that the following approximation holds:

\[
e^{-iHt}/2|1⟩⟩ \simeq e^{-iHt}/2|f_1⟩⟩, \quad e^{iHt}/2|2⟩⟩ \simeq e^{iHt}/2|f_2⟩⟩, \tag{11}
\]

where \( f_1(k) \) and \( f_2(k) \) are certain wave packets from the Hilbert space component \( L^2(\Omega) \) describing intermediate excitonic states. The estimation (11) is equivalent to the existence of wave operators defined as

\[
W_+ = \lim_{t \to +\infty} e^{i\mathcal{H}_0 t} e^{-iHt}, \quad W_- = \lim_{t \to -\infty} e^{-i\mathcal{H}_0 t} e^{iHt} \tag{12}
\]
which holds under mild conditions on the form factors \(g_{1,2}\) and the exciton’s dispersion relation \(\omega(k)\), at least in the weak sense of convergence of matrix elements. Combining (11) with (12), one obtains

\[
f_1(k) = \langle k|W_1|1\rangle, \quad f_2(k) = \langle k|W_-|2\rangle
\]

and finally

\[
A_{12}(t) = \int_{k \in \Omega} dk \ e^{-i\omega(k)t} \langle k|W_1|1\rangle \langle k|W_-|2\rangle.
\]

The advantage of the W–W model is due to the fact that the matrix elements \(\langle 1|W_1|k\rangle\) and \(\langle 2|W_-|k\rangle\) can be exactly computed using Laplace transforms (see the next section).

### 4. The computation of matrix elements

The basic tools used for the computation of the probability amplitude (14) are the identity

\[
e^{-iHt} = e^{-iH_0t} - i \int_0^t ds \{e^{-i\omega(s-t)s}\} \langle g_1(t - s)\rangle \langle 1|1\rangle
\]

\[+ e^{-i\omega(t-t)s}\} \langle g_2(t)\rangle \langle 2|2\rangle\}

where \(g_j(t) \equiv e^{-iH_0t}|g_j\rangle\), and the Laplace transform

\[
f_j(z) = \int_0^\infty e^{-zt} f_j(t) \, dt.
\]

Introducing the notation \((j, j' = 1, 2)\), the definition of the wave operators (12), notation (17) and the Laplace transform, we have

\[
f_1(k) = \langle k|W_1|1\rangle = -i [g_1(k)\tilde{S}_{11}(-i\omega(k)) + g_2(k)\tilde{S}_{21}(-i\omega(k))]\]

\[
f_2(k) = \langle k|W_-|2\rangle = i [g_1(k)\tilde{S}_{22}(-i\omega(k)) + g_2(k)\tilde{S}_{21}(-i\omega(k))].
\]

Combining identity (15) with definitions (17), we obtain a series of equations,

\[
S_{11}(t) = e^{-i\omega_1t} - i \int_0^t e^{-i\omega_1(t-s)} F_{11}(s) \, ds,
\]

\[
S_{22}(t) = e^{-i\omega_2t} - i \int_0^t e^{-i\omega_2(t-s)} F_{22}(s) \, ds,
\]

\[
S_{12}(t) = -i \int_0^t e^{-i\omega_2(t-s)} F_{12}(s) \, ds,
\]

\[
F_{11}(t) = -i \int_0^t G_{11}(t-s) S_{11}(s) \, ds
\]

\[-i \int_0^t G_{12}(t-s) S_{21}(s) \, ds,
\]

\[
F_{22}(t) = -i \int_0^t G_{22}(t-s) S_{22}(s) \, ds
\]

\[-i \int_0^t G_{21}(t-s) S_{12}(s) \, ds,
\]

\[
F_{12}(t) = -i \int_0^t [G_{11}(t-s) S_{12}(s) + G_{12}(t-s) S_{22}(s)] \, ds,
\]

which can be converted into equations for Laplace transforms

\[
\tilde{S}_{11}(z) = \frac{1}{z + i\omega_1} [1 - i\tilde{F}_{11}(z)],
\]

\[
\tilde{S}_{22}(z) = \frac{1}{z + i\omega_2} [1 - i\tilde{F}_{22}(z)],
\]

\[
\tilde{S}_{12}(z) = -\frac{i}{z + i\omega_2} \tilde{F}_{12}(z),
\]

\[
\tilde{S}_{21}(z) = -\frac{i}{z + i\omega_2} \tilde{F}_{21}(z),
\]

\[
\tilde{F}_{11}(z) = -i\tilde{G}_{11}(z)\tilde{S}_{11}(z) - i\tilde{G}_{12}(z)\tilde{S}_{21}(z),
\]

\[
\tilde{F}_{22}(z) = -i\tilde{G}_{22}(z)\tilde{S}_{22}(z) - i\tilde{G}_{21}(z)\tilde{S}_{12}(z),
\]

\[
\tilde{F}_{12}(z) = -i[\tilde{G}_{11}(z)\tilde{S}_{12}(z) + \tilde{G}_{12}(z)\tilde{S}_{22}(z)]
\]

\[
\tilde{F}_{21}(z) = -i[\tilde{G}_{21}(z)\tilde{S}_{11}(z) + \tilde{G}_{22}(z)\tilde{S}_{21}(z)].
\]

The system of equations (20) can be solved yielding the relevant Laplace transforms

\[
\tilde{S}_{11}(z) = \frac{1}{z + i\omega_1 + \tilde{G}_{11}(z)} \left[1 + \frac{\tilde{G}_{12}(z)\tilde{G}_{21}(z)}{W(z)}\right]
\]

\[
\tilde{S}_{12}(z) = -\frac{\tilde{G}_{12}(z)}{W(z)}
\]

\[
\tilde{S}_{21}(z) = -\frac{\tilde{G}_{21}(z)}{W(z)}
\]

\[
\tilde{S}_{22}(z) = \frac{1}{z + i\omega_2 + \tilde{G}_{22}(z)} \left[1 + \frac{\tilde{G}_{12}(z)\tilde{G}_{21}(z)}{W(z)}\right],
\]

where

\[
W(z) = (z + i\omega_1 + \tilde{G}_{11}(z))(z + i\omega_2 + \tilde{G}_{22}(z)) - \tilde{G}_{12}(z)\tilde{G}_{21}(z).
\]

Combining (21) with (18) and (14), one can obtain the exact final formula for the transition amplitude which can be used for numerical calculations. The formulas can be essentially simplified if one neglects all terms containing \(\tilde{G}_{12}(z), \tilde{G}_{21}(z)\). This approximation means that the interaction between the donor and the acceptor mediated by the reservoir is neglected as well as the collective contribution to their relaxation processes. In the case of two atoms in a large cavity, it means that the dipole–dipole interaction and the ‘superradiance/subradiance’ effects [10] are neglected.

### 5. Markovian approximation

In order to continue the analytical analysis of the problem, we consider the case of weak coupling or Markovian approximation and neglect the collective effects as discussed above. The further approximation concerns Laplace transforms \(\tilde{G}_{jj}(z)\). The real part of \(\tilde{G}_{jj}(-i\omega)\), taken at the physical frequency, is the standard Fermi golden rule approximation for the decay rate of the state \(|j\rangle\) \((j = 1, 2)\) given by

\[
y_j = \pi \int_{\Omega} dk |g_j(k)|^2 \delta(\omega(k) - \omega_{\text{ren}}^j),
\]

while the imaginary part is a ‘radiative correction’ to the bare frequencies \(\omega_j\) yielding a physical renormalized frequency

\[
\omega_{\text{ren}}^j = \omega_j - \int_{\Omega} dk |g_j(k)|^2 \mathcal{P} \left(\frac{1}{\omega(k) - \omega_{\text{ren}}^j}\right).
\]
Note that equation (24) has a self-consistent character because \( \omega_j^{\text{ren}} \) appears on both sides of it. It is due to the fact that we cannot expect that the ‘radiative correction’ is small, and hence it is not justified to put the bare value \( \omega_j \) on the rhs of (24) and (23).

Summarizing, the Markovian approximation means that

\[
\tilde{S}_{j1}(-i\omega(k)) \approx 0, \\
\tilde{S}_{ij}(-i\omega(k)) \approx \frac{i(\omega_j^{\text{ren}} - \omega(k)) + \gamma_j}{1 - i\gamma_j}, \quad \gamma_j \ll \omega_j.
\]

Therefore using equations (18) and (25), one obtains

\[
f_1(k) = \frac{g_1(k)}{\omega(k) - \omega_1^{\text{ren}} + i\gamma_1}, \quad f_2(k) = \frac{g_2(k)}{\omega(k) - \omega_2^{\text{ren}} - i\gamma_2}
\]

and

\[
A_{12}(t) = \int_{k \in \Omega} dk \exp(-i\omega(k)t) \\
\times \frac{g_1(k)g_2(k)}{(\omega(k) - \omega_1^{\text{ren}} + i\gamma_1)(\omega(k) - \omega_2^{\text{ren}} + i\gamma_2)}. 
\]

One can estimate the upper bound for \( P_{12}(t) \) using (27) to obtain

\[
P_{12}(t) = |A_{12}(t)|^2 \leq \|f_2\|^2 \|f_1\|^2.
\]

The equality \( \int_{-\infty}^{\infty} |\gamma(x + \gamma^2)^{-1} dx = \pi \) implies for example

\[
\|f_1\|^2 = \int_{\Omega} \|f_1(k)\|^2 \frac{|g_1(k)|^2}{(\omega(k) - \omega_1^{\text{ren}})^2 + \gamma_1^2} \approx \frac{1}{\pi} \int_0^\infty \gamma_1 \frac{1}{(\omega_1^{\text{ren}} - \omega)^2 + \gamma_1^2} \approx 1 - \frac{\gamma_1}{\pi \omega_1}
\]

what finally gives the bound (compare with [8])

\[
P_{12}(t) \leq \left( 1 - \frac{\gamma_1}{\pi \omega_1^{\text{ren}}} \right) \left( 1 - \frac{\gamma_2}{\pi \omega_2^{\text{ren}}} \right) < 1.
\]

In the weak coupling regime, the upper bound is close to 1.

6. Conditions for APET

In order to approach the bound (30) and achieve APET, certain matching conditions implied directly by formula (27) must be satisfied. To present them in a transparent form, we introduce certain additional assumptions in a convenient parametrization. These are satisfied by the two-mirror system discussed in the introduction.

Assume that the intermediate Hilbert space \( L^2(\Omega) \) is spanned by the basis \( |\omega, m\rangle \) and the corresponding part of the Hamiltonian reads

\[
H_1 = \sum_m \int d\omega \omega |\omega, m\rangle \langle \omega, m|.
\]

The form factors possess the following structure:

\[
|g_1\rangle = \int d\omega g(\omega) |\omega, m_0\rangle, \\
|g_2\rangle = \int d\omega e^{-iL(\omega)} g(\omega) |\omega, m_0\rangle
\]

where \( g(\omega) \) is a smooth enough form factor and \( L(\omega) \) accounts for the spatial separation of the donor and the acceptor similar to (2). Now the mechanism leading to APET can be illustrated. We have to put the resonance condition

\[
\omega_1^{\text{ren}} = \omega_2^{\text{ren}} \equiv \omega_0, \tag{33}
\]

which by (23) also implies the equality of decay rates

\[
\gamma_1 = \gamma_2 \equiv \gamma. \tag{34}
\]

Then we have the approximative expression

\[
A_{12}(t) \approx \frac{1}{\pi} \int d\omega \frac{\gamma}{(\omega - \omega_0)^2 + \gamma^2} \times \left( \frac{\omega - \omega_0 - i\gamma}{\omega - \omega_0 + i\gamma} \right)^{2L(\omega) - t}. \tag{35}
\]

Further approximations valid for \( |\omega - \omega_0| \leq \gamma \)

\[
\left( \frac{\omega - \omega_0 - i\gamma}{\omega - \omega_0 + i\gamma} \right)^{2L(\omega) - t} \approx -e^{2i(\omega - \omega_0)/\gamma}, \tag{36}
\]

lead to

\[
|A_{12}(t)| \approx \frac{1}{\pi} \left| \int d\omega \frac{\gamma}{(\omega - \omega_0)^2 + \gamma^2} \times \exp[iL(\omega_0) + 2\tau - t](\omega - \omega_0) \right|, \tag{37}
\]

where \( \tau = 1/\gamma \). The transition probability is maximal and close to 1 if the oscillating factor in the integral of the above vanishes, which happens for the time

\[
t_0 = L(\omega_0) + 2\tau, \tag{38}
\]

which can be called the optimal transfer time.

7. Transport in quantum networks

The standard tight-binding model of energy transport in quantum networks which is applicable both to molecular systems and engineered ones consist of \( N \) 2-level ‘atoms’ described by the Hilbert space \( C^2 \) and the Hamiltonian written in terms of Pauli matrices

\[
H_N = \sum_{k=1}^N \omega_k \sigma_k^z + \sum_{k<l=2}^N (h_{kl} \sigma_k^z \sigma_l^z + \text{h.c.}). \tag{39}
\]

where \( |\omega_k\rangle \) are the energies of the sites and \( |h_{kl}; k < l\rangle \) are the hopping amplitudes. Similar to the example in section 2, the exciton number operator

\[
N_{\text{ex}} = \sum_{k=1}^N (\sigma_k^z + 1/2) \tag{40}
\]

commutes with \( H_N \).
Again a single-exciton \( N \)-dimensional Hilbert space \( \mathbb{C}^N \) is invariant with respect to the dynamics, and the corresponding restriction of the Hamiltonian \( H_N \) is given by the \( N \times N \) Hermitian matrix \([h_{ij}]\) with the diagonal elements \( h_{kk} = \omega_k \). We attribute to the donor site an index ‘1’ and to the acceptor site an index ‘2’. The well-known example of such a model is the standard description of the exciton transfer in the Fenna–Matthews–Olson (FMO) complex which involves \( N = 7 \) centres and the experimentally determined \( 7 \times 7 \) single-exciton Hamiltonian \([11, 12]\).

To describe the influence of environment, different schemes have been proposed mainly based on the Markovian master equations for the reduced density matrix of the exciton system \([3–5, 9]\). Here we propose a different approach based on the W–W model where only the exciton Hamiltonian \([11, 12]\). To describe the influence of other (environmental) degrees of freedom is taken into account. This interaction transforms the eigenstates \(|\alpha\rangle\) into resonances with finite spectral widths. The well-known example of such a model is the discrete version of the W–W Hamiltonian:

\[
H^{(d)} = \omega_0|e_1\rangle\langle e_1| + \omega_2|e_2\rangle\langle e_2| + \omega_3|e_3\rangle\langle e_3| + \ldots + \omega_N|e_N\rangle\langle e_N| + h_1^{(d)}.
\]

Here \(|e_1\rangle = [1, 0, 0, \ldots, 0]\), \(|e_2\rangle = [0, 1, 0, \ldots, 0]\), \(|g_1\rangle = [0, 0, 1, 0, \ldots, 0]\), \(|g_2\rangle = [0, 0, 0, 0, \ldots, 0]\) and \(H_1^{(d)}\) is a submatrix of \(H^{(d)}\) with indices \(k, l = 3, 4, \ldots, N, N + 1\). \(H_1^{(d)}\) can be written in its spectral decomposition form

\[
H_1^{(d)} = \sum_{\alpha=3}^{N+1} \epsilon_{\alpha} |\alpha\rangle\langle \alpha|,
\]

where \(|N + 1\rangle = [0, \ldots, 0, 1]\). The energies \(\epsilon_{\alpha}\) are chosen in a decreasing order which is consistent with the intuition that the energy of a sink \(\epsilon_{N+1}\) should be the lowest one. Note that (41) and (42) can be treated as a discrete version of the continuous spectrum Hamiltonian (9). In the next step, we embed the discrete model into a continuous one. Physically, it means that the interaction with other (environmental) degrees of freedom is taken into account. This interaction transforms the eigenstates \(|\alpha\rangle\) into resonances with finite spectral widths. The Hilbert space spanned by \(|\alpha\rangle|\rangle\) is replaced by \(L^2(\mathbb{R})\) and the Hamiltonian (42) by the multiplication operator by \(\omega_{\alpha}\) which can be formally written as \(H_1 = \int d\omega \omega |\alpha\rangle\langle \alpha|\). Consider the correlation functions characterizing the interaction of the donor–acceptor system with the bath consisting of other sites including a sink site

\[
G_{jj}^{(d)}(t) = \langle g_j | \mathcal{G}(t) | g_j \rangle = \sum_{\alpha=3}^{N+1} |\langle \alpha|g_j\rangle|^2 e^{-\imath \omega_{\alpha}t}, \quad j = 1, 2.
\]

In order to include the interaction with the other degrees of freedom, e.g. vibrational modes for molecular systems like FMO, we assume that the discrete modes \(|\alpha\rangle\) are unstable and the correlations decay with the decoherence rates \(\Gamma_{\alpha}\). The modified correlation functions corresponding to the continuous model read

\[
G_{jj}^{(c)}(t) = \sum_{\alpha=3}^{N+1} |\langle \alpha|g_j\rangle|^2 e^{-\imath \omega_{\alpha}t} e^{-\Gamma_{\alpha}t}, \quad j = 1, 2.
\]

One can replace the discrete form factors \(|\alpha|g_j\rangle\) by the suitable wavefunctions \(g_j(\omega)\) from \(L^2(\mathbb{R})\) satisfying

\[
\text{Re} \left( \int_0^\infty e^{\imath \omega t} G_{jj}(t) \, dt \right) = \sum_{\alpha=3}^{N+1} |\langle \alpha|g_j\rangle|^2 \frac{\Gamma_{\alpha}}{(\omega - \omega_\alpha)^2 + \Gamma_{\alpha}^2} = \pi |g_j(\omega)|^2.
\]

Condition (45) determines only the modulus of \(g_j(\omega)\). The relative phase \(\omega_j\) should be constructed as an interpolation between discrete relative phases for \(|\alpha|g_1\rangle\) and \(|\alpha|g_2\rangle\) defined at the points \(\omega = \omega_\alpha\).

8. Energy transfer controlled by decoherence

The search for the condition which should be satisfied to achieve APET in quantum networks can be treated as a control problem for quantum open systems. One of the possible settings is to treat the tight-binding Hamiltonian (39) as given and optimize the choice of decoherence rates \(\Gamma_\alpha\), acceptor–sink coupling \(h_{2(N+1)}\) and the sink energy \(\epsilon_{N+1}\) to maximize the transition probability \(P_{12}(t_0)\). The advantage of the presented model is a deeper insight into the mechanism of APET based on the discussion in section 6 where analytical formulas are used.

The first condition for APET is a fine-tuning one, namely the resonance condition (33). It can be discussed using the following formula for the renormalized frequencies obtained by putting (44) into (24):

\[
\omega_j^{\text{ren}} = \omega_j - \sum_{\alpha=3}^{N+1} |\langle \alpha|g_j\rangle|^2 \frac{\epsilon_{\alpha} - \omega_j^{\text{ren}}}{(\omega_j^{\text{ren}} - \omega_\alpha)^2 + \Gamma_{\alpha}^2}.
\]

Another condition follows from (34) which implies that \(|g_1(\omega)|\) and \(|g_2(\omega)|\) should essentially coincide in the neighbourhood of \(\omega_0\) of the width \(\gamma \simeq \pi |g_1(\omega_0)|^2 \simeq \pi |g_2(\omega_0)|^2\). One can expect that this condition can be satisfied generically for the widths of the resonances comparable to the typical nearest neighbour energy spacing.

The optimal transfer time estimated from formula (38) reads

\[
t_0 \approx \frac{\pi}{\epsilon_{\omega_0} - \epsilon_{\omega_{N+1}}} + \frac{2}{\pi |g_{1,2}(\omega_0)|^2},
\]

where \(\epsilon_{\omega_0} \gg \omega_0 \gg \epsilon_{\omega_{N+1}}\).

9. Concluding remarks

The 2-state Wigner–Weisskopf model provides a versatile mathematical tool to study, within the single-exciton approach, the transport properties in complex molecular systems or engineered networks relevant for quantum information processing, both in the weak coupling (Markovian) and
strong coupling (non-Markovian) regimes. The preliminary results for the FMO model (work in progress) show that the APET conditions presented here can be achieved under realistic assumptions concerning the decoherence rates and sink parameters. The necessity of fine tuning to achieve APET in disordered molecular networks has already been noticed in [9] where sampling over many molecular configurations has been performed. However, the formalism presented here allows us to design the optimal parameters and shows the details of the physical mechanisms leading to APET. In the case of engineered networks the fine-tuning conditions imply a careful design, while for biologically relevant systems one can imagine that the natural selection mechanism plays a crucial role.
