Abstract

The development of a biofilm constitutes a survival strategy by providing bacteria a protective environment safe from stresses such as microbicidal action and can thus lead to important health-care problems. In this study, biofilm resistance of a Bacillus subtilis strain (called hereafter NDmedical) recently isolated from endoscope washer-disinfectors to peracetic acid was investigated and its ability to protect the pathogen Staphylococcus aureus in mixed biofilms was evaluated. Biocide action within Bacillus subtilis biofilms was visualised in real time using a non-invasive 4D confocal imaging method. The resistance of single species and mixed biofilms to peracetic acid was quantified using standard plate counting methods and their architecture was explored using confocal imaging and electronic microscopy. The results showed that the NDmedical strain demonstrates the ability to make very large amount of biofilm together with hyper-resistance to the concentration of PAA used in many formulations (3500 ppm). Evidences strongly suggest that the enhanced resistance of the NDmedical strain was related to the specific three-dimensional structure of the biofilm and the large amount of the extracellular matrix produced which can hinder the penetration of peracetic acid. When grown in mixed biofilm with Staphylococcus aureus, the NDmedical strain demonstrated the ability to protect the pathogen from PAA action, thus enabling its persistence in the environment. This work points out the ability of bacteria to adapt to an extremely hostile environment, and the necessity of considering multi-organism ecosystems instead of single species model to decipher the mechanisms of biofilm resistance to antimicrobials agents.

Introduction

In response to environmental conditions, bacteria have developed different strategies to adapt and survive. The formation of multicellular communities known as biofilms is one such strategy, which is associated with increased bacterial resistance to environmental stress accompanying antimicrobial treatments [1,2]. It has indeed been shown that non-lethal concentrations of antibiotics or disinfectants can stimulate biofilm formation [3,4] which constitutes a defensive response to the toxic effects of the biocides. Mechanisms involved in the resistance of biofilms remain unclear but appear to result from multifactorial processes related to the architecture of the edifice and the phenotypic features of the cells. The presence of a protective extracellular matrix via the expression of specific genes in the biofilm, the metabolic state of cells due to microenvironmental conditions have all been identified as playing a role in biofilm resistance to antimicrobial agents [5]. In the clinical settings, biofilms promote infection through, for example, the persistence of bacteria on medical devices and thus can act as reservoir for pathogens [6,7]. It has been estimated that 65% of nosocomial infections directly involve biofilms [8]. Of all medical devices used, flexible endoscopes are among the most frequently associated with outbreaks of infectious organisms [9,10,11,12,13]. Indeed, some studies have reported the presence of persistent bacteria on endoscopes despite cleaning and disinfection procedures [14,15]. Interestingly, a viable strain of B. subtilis was recently isolated from an endoscope washer-disinfector after high level disinfection with chlorine dioxide [16]. The authors showed that this isolate had developed cross-resistance against other oxidising agents using a standard suspension test. Recently, we showed that this stable isolate was able to produce a thick immersed biofilm with specific protruding structures [17]. In this work, we have now investigated the resistance of this strain in biofilm to peracetic acid (PAA), an oxidizing agent commonly used in formulations used for endoscope disinfection. In addition, we examined the ability of the NDmedical strain to protect Staphylococcus aureus, a pathogen responsible of a large number of hospital acquired infections [18], from biocidal action in a mixed biofilm.
Materials and Methods

Bacterial Strains and Growth Conditions

The bacterial strains used in this study are listed in Table 1. The GFP-carrying Bacillus subtilis ND\textsubscript{medical} strain was obtained by transforming B. subtilis ND\textsubscript{medical} to spectinomycin resistance with chromosomal DNA of strain GM2812 [17], thus placing in the \textit{amyE} locus the \textit{gfp} (mut2) gene under the control of the IPTG-regulated \textit{P\textsubscript{phyto}B} promoter. Transformation was performed according to standard procedures and the transformants were selected on Luria-Bertani (LB, Sigma, France) plates supplemented with spectinomycin at 100 \(\mu\)g/ml. Before each experiment, bacteria were subcultured twice in Tryptone Soya Broth (TSB, BioMerieux, France). When necessary, IPTG at a final concentration of 200 \(\mu\)M was added to the medium to induce GFP production, and antibiotics at the following concentrations: spectinomycin, 100 \(\mu\)g/ml; erythromycin, 3 \(\mu\)g/ml.

Biofilms Architecture

Confocal Laser Scanning Microscopy (CLSM). Biofilms were formed in polystyrene 96-well microtiter plates with a \(\mu\)clear\textsuperscript® base (Greiner Bio-one, France) enabling high-resolution fluorescence imaging as previously described [19]. For single species biofilms, 250 \(\mu\)l of an overnight culture in TSB adjusted to an OD\textsubscript{600nm} of 0.02 were added to the wells of the microtiter plate. For mixed species biofilm, overnight cultures in TSB of \textit{S. aureus} AH478 mCherry and the \textit{B. subtilis} GFP strains were adjusted to an OD\textsubscript{600nm} of 0.02 in TSB and mixed at a ratio of 1:2. The microtiter plate was then kept at 30°C for 90 min to form biofilm development. After development, biofilms were washed with 150 mM NaCl and series of xy images with a z-step of 1 \(\mu\)m were obtained to analyze the three-dimensional structure of the biofilms. Both single and mixed biofilms were scanned using an excitation wavelength of 458 nm (argon laser, 25% intensity) and 543 nm (helium-neon laser, 50% intensity), with emission wavelengths collected from 480 to 530 nm and from 580 to 700 nm respectively for GFP and mCherry fluorescence. Three-dimensional projections of biofilm structures were reconstructed using the Easy 3D function of the IMARIS 7.0 software (Bitplane, Switzerland) directly from xy images series.

Scanning Electronic Microscopy (SEM). For SEM observations, \textit{B. subtilis} biofilms were prepared by immersing coupons in the wells of a 24-well polystyrene plate containing bacterial suspensions adjusted to an OD\textsubscript{600nm} of 0.2. After 90 min of adhesion, coupons were rinsed and wells were refilled with 1 ml of TSB. The plate was then incubated at 30°C for 24 h. After development, biofilms were rinsed with 150 mM NaCl and attached bacterial cells were fixed in a solution containing 2.5% glutaraldehyde, 0.1 M sodium cacodylate (pH 7.4), 0.075% ruthenium red and 0.015% Alcian blue for 20 h. Ruthenium red and Alcian blue were added to the fixing solution because it have been showed that their presence could promote the visualization of extrapolymeric substances such as biofilm matrix components [20,21]. Samples were then washed three times for 10 min with a solution containing 0.1 M sodium cacodylate, 0.075% ruthenium red and 0.015% Alcian blue before being transferred into 50% ethanol. Samples were progressively dehydrated by passage through a graded series of ethanol solutions from 50% to 100%. Finally, the samples were critical point dehydrated (Emitech K850, UK) using carbon dioxide as the transition fluid and coated with gold-palladium in an automatic sputter coater (Polaron SC7640, UK). Scanning electron microscopy Quanta 650 FEG-SEM (FEI, Japan) was used to observe the samples.

Congo red indicator assay on macrocolonies. The morphology of macrocolonies formed by both \textit{B. subtilis} strains and their Congo Red binding properties were tested using indicator agar plates. Experimentally, 5 \(\mu\)l of an overnight culture in TSB were inoculated on TS agar (1.5%) containing 40 \(\mu\)g/ml Congo Red (Sigma-Aldrich, France). Plates were then incubated for 72 h at 30°C.

Determination of the sugar and protein contents of the biofilm matrix. The protein and sugar levels of the matrix of \textit{B. subtilis} 168 and ND\textsubscript{medical} biofilms were determined after 24 h of development in TSB. Biofilms were rinsed in distilled water and recovered from the microtiter plate by scraping the bottom of the wells with tips and aspirating and expelling the suspension at least 10 times. The suspensions were then vortexed during 30 seconds before being centrifuged at 4000 g for 20 minutes. After, the supernatants were transferred in sterile tubes and vortexed 30 seconds before being kept at 20°C until biochemical assays were performed. Protein contents were evaluated using the Bradford assay [22] with bovine serum albumin as the standard. Sugar levels were determined by using the phenol-sulfuric acid assay procedure [23] with glucose as the standard. Each experiment was performed in triplicate on three independent biofilm extractions.

Biocide Treatments

Biocide testing. After development, biofilms in the microtiter plates were rinsed and the wells refilled with 100 \(\mu\)l of TSB. Then, 100 \(\mu\)l of peracetic acid (PAA) (32 wt. % in dilute acetic acid (Sigma-Aldrich, France)) at 7000 ppm were then added in the wells to obtain a final concentration of 3500 ppm. After 5 min of contact, biocide solutions were gently removed and wells were refilled with a quenching solution (3 g/L L-\(\alpha\)-phosphatidyl cholin, 30 g/L Tween 80, 5 g/L sodium thiosulfate, 1 g/L L-histidine, 10 min with a solution containing 0.1 M sodium cacodylate, 0.075% ruthenium red and 0.015% Alcian blue before being transferred into 50% ethanol. Samples were progressively dehydrated by passage through a graded series of ethanol solutions from 50% to 100%. Finally, the samples were critical point dehydrated (Emitech K850, UK) using carbon dioxide as the transition fluid and coated with gold-palladium in an automatic sputter coater (Polaron SC7640, UK). Scanning electron microscopy Quanta 650 FEG-SEM (FEI, Japan) was used to observe the samples.

Table 1. Strains used in this study.

| Strain       | Relevant genotype or description * | Reference or construction          |
|--------------|-----------------------------------|------------------------------------|
| \textit{B. subtilis} 168 | trpC2                             | Bacillus Genetic Stock Center      |
| \textit{B. subtilis} 168 GFP | amyE::PhyPspank-gfp (specR)         | [17]                               |
| \textit{B. subtilis} ND\textsubscript{medical} | Freshly isolated from endoscope washer-disinfectors | [16]                               |
| \textit{B. subtilis} ND\textsubscript{medical} GFP | amyE::PhyPspank-gfp (specR)         | \textit{B. subtilis} GM2812 [17] ND\textsubscript{medical} |
| \textit{S. aureus} AH478 | Strain RN4220 with a plasmid harbouring a mCherry gene (eryR) | [18]                               |

*spec and ery stand for spectinomycin and erythromycin resistance markers respectively. doi:10.1371/journal.pone.0044506.t001
30 g/L saponine) and left for 5 min to stop biocide action. The bottom of the wells was then scraped with tips and the suspension aspirated and expelled many times to detach and recover survivor cells from biofilms. The suspensions were then serially diluted in 150 mM NaCl and plated on Tryptone Soya Agar (TSA, Biomerieux, France) before being incubated at 30°C for 24–48 h.

To determine the sensitivity of B. subtilis ND medical to PAA following disruption of the biofilm, biofilms were rinsed with TSB and cells were recovered by scraping the bottom of the wells with tips and aspirating and expelling many times the suspension. The recovered cells were mixed with 150 mM NaCl containing glass beads and suspension vortexed for 30 s to separate cells and extracellular matrix. The suspension was then washed after centrifugation (7000 g, 10 min, 20°C) and adjusted to 10⁶ CFU/ml in 150 mM NaCl. In parallel, planktonic bacteria were harvested from a 24 h culture in TSB at 30°C by centrifugation (7000 g, 10 min, 20°C) followed vortexing with glass beads (0.5 mm of diameter) for 30 s and then washed in 150 mM NaCl before also adjusting to 10⁶ CFU/mL. Peracetic acid activity was then evaluated according to the standard European NF EN 1040 procedure [24] at a final concentration of 5 ppm with the adjusted cell suspension. Survivors were counted after incubation by comparing the number of colonies with those obtained when biocide was replaced by distilled water. Each experiment was done in triplicate.

In parallel, the susceptibility to peracetic acid at 5 ppm of planktonic suspensions of B. subtilis 168, B. subtilis ND medical and S. aureus AH478 was evaluated. The resistance of S. aureus AH478 suspension in absence or presence of extracellular matrix extracted from B. subtilis 168 or ND medical biofilm was also determined. In this aim, biofilm matrix extracts were directly added to S. aureus AH478 suspension at a 1:10 (vol/vol) concentration before disinfection step according to the NF EN 1040 standard procedure. Finally, we determined the susceptibility of mixed suspensions of S. aureus with B. subtilis 168 or ND medical strain to evaluate to potential role of a soluble effector in the resistance of the pathogen in mixed communities. In this end, S. aureus AH478 and B. subtilis 168 or ND medical were grown together in TSB overnight before peracetic acid treatment at 5 ppm using NF EN 1040 standard procedure.

**Real-time visualization of PAA activity in biofilms.** Time lapse CLSM analysis of PAA action was performed in B. subtilis biofilms as previously described [25]. This technique permits the direct visualization of cell inactivation patterns in biofilm structures during biocide action. The method is based on the monitoring of fluorescence loss caused by the leakage of an unbound fluorophore outside the cells after disruption of the bacterial membrane by antimicrobial agents. Experimentally, 24 h biofilms in a microtiter plate were rinsed with TSB in order to eliminate planktonic cells. The wells were then refilled with 100 µl of TSB containing Chemchrome V6 (1:100 of commercial solution (AES Chemunex, France)). Chemchrome V6 is an esterasic marker which enter cells passively and is then cleaved by cytoplasmic esterases, leading to the intracellular release of fluorescent residues (green fluorescence). Microtiter plates were incubated in the dark at 20°C for 1 h in order to reach fluorescence equilibrium. Biofilms were then rinsed to eliminate excess Chemchrome V6 and refilled with 100 µl of TSB. The microtiter plate was then mounted on the motorized stage of a Leica TCS SP2 AOBS Confocal laser scanning microscope (LEICA Microsystems, France) at the MIMA2 microscopy platform (http://voxel.jouy.inra.fr/mima2). The CLSM control software was set to take a series of time-lapse xyzt scans (256 x 256 pixels) at intervals of 15 s at five different depths in the biofilm. Biofilms were scanned at 400 Hz using a 63 x oil objective with a 1.4 numerical aperture with a 488 nm argon laser set at 10% of its maximal intensity. These settings, which were shown to avoid photobleaching of the sample by performing preliminary scans using distilled water instead of biocides, were used in all time-lapse experiments. Emitted V6 Chemchrome green fluorescence was recorded within the range 500–600 nm. After the starting of the xyzt scan series, 100 µl of PAA at 7000 ppm were gently added to the wells just after the completion of the first scan. Biofilms were then scanned every 15 s at five different depths over 10 min, and fluorescence loss within the structure was recorded. Three independent experiments were performed for each strain.

**Quantification of green fluorescence intensity from the time-lapse (xyzt) CLSM image series was performed using confocal software LCS Lite (Leica Microsystems, France).** Intensity values were then normalized by dividing the fluorescence intensity recorded by the initial fluorescence intensity value at the same location. Fluorescence intensity curves shown are the mean of three experiments, each experiment constituting the average of five horizontal sections along the depth of the biofilm.

**Application of bacterial destruction models on fluorescence intensity curves.** GinaFIT, a freeware Add-in for Microsoft® Excel developed by Geeraerd et al. [26] was used to modelize inactivation kinetics. This tool enables testing of nine different types of microbial survival models, and the choice of the best fit depends on five statistical measures (i.e., sum of squared errors, mean sum of squared errors and its root, R², and adjusted R²). During this study, the “log-linear + tail” inactivation model was fitted on fluorescence intensity curves obtained from CLSM image series during biocide treatment. The inactivation rate k max (min⁻¹) was extracted from the fitting.

**Determination of spores.** In order to check the presence of spores in the biofilm after 24 h of development, cells were recovered from the microtiter plates as described above and resuspended in 150 mM NaCl and boiled at 100°C for 10 min. Bacterial numbers (cfu/ml) were determined before and after the heat treatment.

**Statistical Analysis**

One-way ANOVA was performed using Statgraphics v6.0 software (Manugistics, Rockville, USA). Significance was defined as a P value associated with a Fisher test value lower than 0.05.

**Results**

**Phenotypic Characterization of Biofilms Formed by ND medical and 168 Strains**

Biofilms formed by a non-domesticated B. subtilis strain (ND medical) recently isolated from an endoscope washer-disinfector and by the laboratory B. subtilis 168 strain were characterized. First, the architecture of biofilms formed by both B. subtilis GFP strains was observed after 24 h of development using CLSM as presented in Fig. 1A. The images correspond to three-dimensional reconstructions obtained from confocal stack images by the IMARIS software, including virtual shadow projections on the right. In accordance with previously published observations [17], we found that the non-domesticated B. subtilis ND medical strain clearly developed a thicker biofilm with protruding structures in comparison to strain 168 in these experimental conditions.

In order to visualize the extracellular material produced in biofilms of both B. subtilis 168 and the ND medical strains, SEM observations were also performed. In both cases, the extracellular material detected appeared to be composed of tangled thread-like strands forming a complex network. However, this was clearly much denser in the biofilm of the ND medical strain as shown in
It should be noted here that SEM observations required several dehydration steps during sample preparation and therefore the electron micrographs can not be considered as faithful representations of fully hydrated biofilms. However, these results clearly indicated the presence of larger amount of extracellular substances in ND medical strain biofilm in comparison to strain 168. Since Congo Red is known to bind extracellular substances, it has been widely used in previous works to compare the ability of different strains to produce extracellular components in numerous bacterial species including B. subtilis [27,28,29]. Macrocolonies of both B. subtilis strains grown for 72 h on Congo Red indicator plates are presented in Fig. 1C. We observed that ND medical produced highly wrinkled macrocolonies as compared to strain 168. In addition, the ND medical strain stained red more intensively on Congo Red indicator plates, suggesting a higher amount of exopolymeric substances.

In line with this, biochemical quantification of the extracellular matrix confirmed that ND medical produced more abundantly extracellular components than strain 168. Indeed, sugar and protein contents of biofilm matrix reached respectively 33.5 ± 1.4 and 26.7 ± 1.0 mg/l for ND medical strain whereas these values attained only 13.1 ± 0.8 and 8.7 ± 0.3 mg/l for the strain 168.

B. subtilis ND medical Biofilms Exhibit a Marked Resistance to PAA

The resistance of biofilms formed by both B. subtilis strains exposed to 3500 ppm of PAA for 5 min was then investigated. These conditions represent the in-use PAA concentration and time of exposure commonly used in hospitals for the disinfection treatment of endoscopes. The results showed substantial resistance of the B. subtilis ND medical strain which exhibited only 3.8 log of reduction while no survivor were detected on plates for strain 168, corresponding to a reduction greater than 5.6 log (Table 2). Using thermic treatment, we confirmed that ND medical biofilm did not contain any spores at 24 h of development showing that the resistance observed was displayed by vegetative cells.

The resistance of the ND medical biofilm was investigated further by time-lapse CLSM microscopy allowing to visualize biocide action in real-time within the biofilm structures of both B. subtilis

Table 2. Bactericidal activity of water and 0.35% PAA on single and mixed species biofilms after 5 min of treatment.

| Strain                  | log (CFU/well) | PAA (0.35%) |
|-------------------------|----------------|-------------|
| **Single species biofilm** |                |             |
| B. subtilis 168         | 7.6±0.2        | –           |
| B. subtilis ND medical  | 7.7±0.1        | 3.9±0.6     |
| S. aureus AH478         | 9.3±0.1        | –           |
| **Mixed species biofilm** |                |             |
| B. subtilis 168         | 7.5±0.5        | –           |
| S. aureus RN4220        | 8.2±0.4        | –           |
| B. subtilis ND medical  | 7.3±0.3        | 3.9±0.3     |
| S. aureus RN4220        | 8.4±0.1        | 2.6±0.5     |

Data shown are mean of three experiments ± standard deviation. Samples from which no survivor were recovered are represented by (−). Minimum detection of 2 logs CFU/well.

Fig. 1B. It should be noted here that SEM observations required several dehydration steps during sample preparation and therefore the electron micrographs can not be considered as faithful representations of fully hydrated biofilms. However, these results clearly indicated the presence of larger amount of extracellular substances in ND medical strain biofilm in comparison to strain 168. Since Congo Red is known to bind extracellular substances, it has been widely used in previous works to compare the ability of different strains to produce extracellular components in numerous bacterial species including B. subtilis [27,28,29]. Macrocolonies of both B. subtilis strains grown for 72 h on Congo Red indicator plates are presented in Fig. 1C. We observed that ND medical produced highly wrinkled macrocolonies as compared to strain 168. In addition, the ND medical strain stained red more intensively on Congo Red indicator plates, suggesting a higher amount of exopolymeric substances.

In line with this, biochemical quantification of the extracellular matrix confirmed that ND medical produced more abundantly extracellular components than strain 168. Indeed, sugar and protein contents of biofilm matrix reached respectively 33.5 ± 1.4 and 26.7 ± 1.0 mg/l for ND medical strain whereas these values attained only 13.1 ± 0.8 and 8.7 ± 0.3 mg/l for the strain 168.

B. subtilis ND medical Biofilms Exhibit a Marked Resistance to PAA

The resistance of biofilms formed by both B. subtilis strains exposed to 3500 ppm of PAA for 5 min was then investigated. These conditions represent the in-use PAA concentration and time of exposure commonly used in hospitals for the disinfection treatment of endoscopes. The results showed substantial resistance of the B. subtilis ND medical strain which exhibited only 3.8 log of reduction while no survivor were detected on plates for strain 168, corresponding to a reduction greater than 5.6 log (Table 2). Using thermic treatment, we confirmed that ND medical biofilm did not contain any spores at 24 h of development showing that the resistance observed was displayed by vegetative cells.

The resistance of the ND medical biofilm was investigated further by time-lapse CLSM microscopy allowing to visualize biocide action in real-time within the biofilm structures of both B. subtilis

strains. Figure 2A presents the dynamics of fluorescence loss (membrane permeabilization) within the biofilms during treatment with 500 ppm of PAA. This concentration was chosen in order to enable the visualization of biofilm damage in approximately 10 min. When biofilms were treated with distilled water as a control, the loss of fluorescence observed was less than 1% (n = 4) of the initial fluorescence after 10 min of treatment. The GimaFIT “log linear + tail” inactivation model [26] was applied to these experimental data to extract the inactivation rate $k_{\text{max}}$ and this revealed a satisfactory adjustment ($R^2$ > 0.982). The results confirmed the greater resistance of the biofilm for strain ND$_{\text{medical}}$ compared to the laboratory strain 168. While PAA treatment resulted in an immediate and uniform loss of fluorescence of cells in the biofilm for strain 168, the loss of fluorescence in the ND$_{\text{medical}}$ biofilm was slow and heterogeneous during disinfection treatment. The extracted $k_{\text{max}}$ inactivation rates showed a large and significant difference between strain 168 and ND$_{\text{medical}}$ (inset in Fig. 2B) with values of 14.0 and 0.4 respectively. Spatial patterns of fluorescence loss in biofilms treated with 500 ppm PAA are presented in Figure 2B. A homogeneous and sharp loss of fluorescence was seen in the whole biofilm structure of strain 168 following the application of biocide. Conversely, PAA application led to a non-homogenous loss of fluorescence within the biofilm structure of the ND$_{\text{medical}}$ strain. Indeed, with this strain, we observed that spreading of PAA was difficult in some areas and these remained fluorescent even after 10 min of treatment, illustrating the high resistance and associated low inactivation rate $k_{\text{max}}$ displayed by this strain.

The resistance to PAA (5 ppm) of cells following removal and washing from the biofilm of strain ND$_{\text{medical}}$ was investigated and compared to the resistance of the corresponding planktonic cells. Reductions of $2.9 \pm 0.3$ and $2.8 \pm 0.1$ log (cfu/ml) were obtained for planktonic cells and detached cells respectively i.e. no significant difference ($P > 0.05$). The disruption of the biofilm and at least partial elimination of extracellular substances thus led to the disappearance of the PAA resistance.

The ND$_{\text{medical}}$ Strain Provides Protection to S. aureus Against PAA in a Mixed Biofilm

The previous results showed that the ND$_{\text{medical}}$ biofilm exhibited marked resistance to PAA treatment and suggested that the extracellular matrix likely plays an important role in this resistance. We next investigated whether the ND$_{\text{medical}}$ biofilm can provide protection in a mixed biofilm to S. aureus, a pathogenic strain present in medical environments and often incriminated in nosocomial infections.

As shown on Fig. 3A, S. aureus alone produced flat and regular biofilm with a thickness of 20–30 μm. When this single species biofilm was exposed to 3500 ppm of PAA for 5 min, the small numbers of survivors on plates corresponded to a more than 7.3 log of reduction compared to distilled water control (Table 2). However, when growing in a mixed biofilm with B. subtilis ND$_{\text{medical}}$, the same PAA treatment produced a 5.9 log reduction of S. aureus suggesting that pathogenic strain acquired benefit from strain association. Note that B. subtilis ND$_{\text{medical}}$ resistance to PAA was similar in both single and mixed biofilms with 3.8 and 3.4 log reduction respectively. In contrast, mixed biofilm composed of the lab strain B. subtilis 168 and S. aureus AH478 did not gain a higher resistance to PAA compared to the single species biofilms.

Confocal observations showed that, in the presence of S. aureus AH478, B. subtilis ND$_{\text{medical}}$ was able to develop three-dimensional structures similar to those observed in the single species biofilm of this strain (Fig. 3B). The S. aureus cells largely covered the surface of the bottom of the wells not occupied by the B. subtilis strain although some cells were trapped in the protruding structures formed by the ND$_{\text{medical}}$ strain.

Interestingly, when B. subtilis ND$_{\text{medical}}$ biofilm matrix extract was added to a S. aureus AH478 suspension before peracetic treatment at 5 ppm, we enumerated survivors on Petri dishes with a reduction of $3.6 \pm 0.3$ log whereas no survivor (log reduction > 4.1 log) was observed when matrix extract from B. subtilis 168 biofilm was added to S. aureus AH478 suspension in the same conditions. When examining the resistance of mixed overnight culture of S. aureus AH478 with each B. subtilis strains to peracetic acid, we did not observed, in both cases, a significant better resistance of the pathogen compared to single S. aureus culture ($P > 0.05$).

Together, these results underline that a direct interaction of ND$_{\text{medical}}$ biofilm matrix components with peracetic acid likely plays a key role in the better resistance of S. aureus AH478 observed in mixed biofilm.

Discussion

In a previous study, Martin et al. [16] isolated a strain of B. subtilis (called ND$_{\text{medical}}$ in this study) from an endoscope washer-disinfector and showed that this strain developed a high resistance against various oxidizing agents using a standard suspension test. On the basis of SEM observations, they suggested that this resistance could be due to a higher production of matrix in comparison with sensitive strains. Recently, we showed that this stable isolate produces a very thick biofilm with specific protruding and elevated structures in comparison to other B. subtilis strains [17], and this was confirmed in our present observations. As biofilm formation is frequently associated with increased resistance to sanitizing treatments and antibiotic therapies [30,31,32], the enhanced biofilm-forming ability of strain ND$_{\text{medical}}$ can thus represent a strategy to survive despite the regular exposure to biocide treatments. In line with this, Shemesh et al. [4] showed that sublethal doses of chlorine actually stimulated biofilm formation by B. subtilis, reflecting an apparent defensive response against biocide action. In addition, it has been shown in P. aeruginosa that hyper-biofilm forming variants appear due to self-generated diversity occurring in the biofilm, and this was correlated with higher resistance of the whole community to hydrogen peroxide [33]. Our present results showed a very high resistance of the ND$_{\text{medical}}$ biofilm to PAA, an oxidizing agent commonly used in formulations used in endoscope disinfection; highlighting that biofilm formation could indeed enable this strain to persist despite drastic disinfection treatments applied during endoscope decontamination. Some evidence appears to suggest that this high resistance could be mainly related to an increased production of extracellular matrix in agreement with the previous observations made by Martin et al. [16] with planktonic cells. First, the disruption of the three-dimensional biofilm structure and washing of cells led to the restoration of a PAA sensitivity similar to that observed for planktonic cells. In addition, SEM observations and Congo red assays showed that the ND$_{\text{medical}}$ strain produced a denser and more abundant extracellular substances when compared with strain 168, which was much more sensitive to PAA. Finally, biochemical assay showed that sugars and proteins contents in ND$_{\text{medical}}$ biofilm were respectively 2.6 and 3.1 times higher than in the biofilm formed by the strain 168. These results highlight the primordial role of the three-dimensional structure of the biofilm of ND$_{\text{medical}}$ strain and the abundant matrix that could play a protective role through the interaction with and the quenching of PAA reducing thus its penetration into the biofilm. Previous studies reported that penetration limitations encountered.
Figure 2. Real-time visualization of PAA (0.05%) activity in B. subtilis biofilms. (A) Quantification of Chemchrome V6 fluorescence intensity in B. subtilis 168 (white squares) and ND<sub>medical</sub> (black squares) biofilms during PAA treatment at 500 ppm. Values shown corresponds to the average of the fluorescence at five depths with standard deviation in the biofilm for a representative experiment. Inactivation rate $k_{\text{max}}$ was obtained after fitting GinaFIT “log linear + tail” inactivation model on experimental data. The means of three experiments ± standard deviation are presented in the inset. (B) Visualization of Chemchrome V6 fluorescence loss (membrane permeabilisation) in B. subtilis 168 and ND<sub>medical</sub> biofilms at 0. 15 and 30 seconds and 0. 5 and 10 minutes respectively during PAA treatment (0.05%). Each image corresponds to the superimposition of a green fluorescence image of a representative experiment on a greyscale image of initial fluorescence at the same location. Scale bars correspond to 20 µm. doi:10.1371/journal.pone.0044506.g002
by chlorine, another oxidising agent, in biofilms of different species can explain at least partly the reduced activity of this molecule probably due to interactions with biofilm constituents [34,35,36]. Kinetic profiles and spatial patterns of fluorescence loss (cell membrane permeabilization) obtained using CLSM time lapse visualization of PAA action in the ND medical biofilm (Fig. 2) were consistent with these observations. Indeed, the progressive action of PAA in the heterogeneous structure of biofilm, with cells in some internal areas remaining fluorescent even after 10 min of treatment illustrate the limited action of the biocide in these areas. In line with these observations, we can hypothesize that the presence of dense matrix domains in the ND medical biofilm may constitute the principal mechanism involved in resistance to PAA. Whether this phenotype is related to one or several matrix components needs to be addressed. In particular, the involvement of molecular constituents already known to participate to the matrix composition of B. subtilis such as epsA-O operon products [37,38] or TasA amyloid fibers [29,39] for the most clearly identified, should be investigated. The nucleotide sequences of the epsA-O and yqxA/sipW/tasA operons, including their promoter regions, were identical in both the ND medical and 168 strains (data not shown). In addition, construction of transcriptional fusion genes with a fluorescent reporter associated with flow-cytometry showed no significant difference between expression of the epsA-O operon in ND medical and 168 strains, whereas expression of the yqxA/sipW/tasA operon was significantly higher in biofilms of the reference strain as compared to the ND medical strain (P<0.05, data not shown). Taken together, these data indicated that the resistance observed of the strain ND medical was likely not due to modification of any of these major elements involved in the B. subtilis matrix composition, but rather to different genes that remain to be identified.

We also investigated whether S. aureus can be protected from disinfection in a mixed biofilm with B. subtilis ND medical strain. S. aureus is a bacterial pathogen commonly found in hospitals and responsible for a large number of infections [18,40], and numerous studies have reported the presence of S. aureus on endoscopes even after disinfection procedures [15,41]. Our results demonstrated that more than 7.3 log of reduction (no survivor enumerated) were obtained for S. aureus single species biofilm after PAA treatment at 3500 ppm whereas we found only 5.9 log of reduction when growing in mixed biofilm with ND medical strain (Table 2). These results showed a protective effect of the presence of B. subtilis ND medical strain to S. aureus against PAA activity. Confocal images revealed that some S. aureus cells were entrapped in the protruding structures formed by the ND medical strain and thus probably benefited from the protective matrix of the B. subtilis strain. Supporting this hypothesis, addition of B. subtilis ND medical biofilm matrix extract to a S. aureus AH478 planktonic suspension led to a better resistance of the pathogen to peracetic acid. Moreover, since the concomitant growth of S. aureus with the ND medical strain in suspension had no effect on the resistance of S. aureus, it is likely that the higher survival of S. aureus in mixed biofilm was mainly due to the quenching of the oxidizing agent by the abundant extracellular matrix produced by the B. subtilis ND medical strain, rather than a soluble effector which could trigger the pathogen resistance. Different works already reported that species associations in mixed biofilms can result in a higher resistance to disinfection compared to single species biofilms [42,43,44,45,46] and that some species can protect another throughout interspecies spatial associations. Leriche et al. [47] reported for instance that Staphylococcus scvis was protected in a mixed biofilm against a chlorinated solution by microcolonies formed by Kocuria sp., a more resistant strain. As it is clear that microbial communities present in medical or industrial areas are complex multispecies associations rather than controlled single species model, these findings highlight the importance to challenge biocides on representative multispecies biofilm models of the environment considered. In this study, peracetic acid alone was tested but it should be highlighted that further studies are required to understand the impact on PAA-containing formulations. Product formulations can vary considerably on their activity against biofilms due to presence of other chemicals, such as chelating agents and detergents. These can help detach and disaggregate the biofilms, thus facilitating biocidal activity.

In conclusion, this work points out that the selection pressure maintained in healthcare environments by regular disinfection treatments can lead to the emergence of strains with hyper-resistance phenotypes. This is related to the great ability of bacteria to adapt to their environments by developing efficient survival strategies such as biofilm formation. Particular attention should thus be paid to the choice of strains which are representative of the reality of medical areas in disinfectant testing. In addition, the necessity to consider the resident microbial ecosystem (including non-pathogenic but resistant strains as B. subtilis ND medical) instead of pathogen alone is emphasized since the persistence of a strain can be related not directly to its intrinsic resistance but also to the interactions with other species present in

the environment. Future works will focus on the understanding of the adaptation mechanisms leading to an increased resistance of bacteria to biocides in these environments.

Acknowledgments

We would like to thank Dr. C.L. Malone for S. aureus AH478 mCherry strain. Barry Holland is warmly acknowledged for the English revision of the text.
