ABSTRACT

\textbf{Aims.} Observations of the molecular gas over scales of \(\sim 0.5\) to several kpc provide crucial information on how molecular gas moves through galaxies, especially in mergers and interacting systems, where it ultimately reaches the galaxy center, accumulates, and feeds nuclear activity. Studying the processes involved in the gas transport is one of the important steps forward to understand galaxy evolution.  

\textbf{Methods.} \(^{12}\)CO, \(^{13}\)CO 1–0, and \(^{18}\)O high-sensitivity ALMA observations (\(-4'' \times 2''\)) were used to assess the properties of the large-scale molecular gas reservoir and its connection to the circumnuclear molecular ring in the merger NGC 1614. Specifically, the role of excitation and abundances were studied in this context. We also observed the molecular gas high-density tracers CN and CS.

\textbf{Results.} The spatial distributions of the detected \(^{12}\)CO 1–0 and \(^{13}\)CO 1–0 emission show significant differences. \(^{12}\)CO traces the large-scale molecular gas reservoir, which is associated with a dust lane that harbors infalling gas, and extends into the southern tidal tails. \(^{13}\)CO emission is – for the first time – detected in the large-scale dust lane. In contrast to \(^{12}\)CO, its line emission peaks between the dust lane and the circumnuclear molecular ring. A \(^{12}\)CO-to-\(^{13}\)CO 1–0 intensity ratio map shows high values in the ring region (\(\sim 30\)) typical for the centers of luminous galaxy mergers and even more extreme values in the dust lane (\(>45\)). Surprisingly, we do not detect \(^{18}\)O emission in NGC 1614 – but we do observe gas emitting the high-density tracers CN and CS.

\textbf{Conclusions.} We find that the \(^{12}\)CO-to-\(^{13}\)CO 1–0 line ratio in NGC 1614 changes from \(>45\) in the 2 kpc dust lane to \(\sim 30\) in the starburst nucleus. This drop in ratio with decreasing radius is consistent with the molecular gas in the dust lane being kept in a diffuse, unbound state while it is being funneled towards the nucleus. This also explains why there are no (or very faint) signs of star formation in the dust lane, despite its high \(^{12}\)CO-luminosity. In the inner 1.5 kpc, the gas is compressed into denser and likely self-gravitating clouds (traced by CN and CS emission), allowing it to power the intense central starburst. We find a high \(^{16}\)O-to-\(^{18}\)O abundance ratio in the starburst region (\(\geq 900\)), typical of quiescent disk gas. This is surprising since, by now, the starburst is expected to have enriched the nuclear interstellar medium in \(^{18}\)O relative to \(^{16}\)O. We suggest that the massive inflow of gas may be partially responsible for the low \(^{16}\)O-to-\(^{18}\)O abundance since it will dilute the starburst enrichment with unprocessed gas from greater radial distances. The \(^{12}\)CO-to-\(^{13}\)CO abundance of \(>90\) we infer from the line ratio is consistent with this scenario. It suggests that the nucleus of NGC 1614 is in a transient phase of its evolution where the starburst and the nuclear growth is still being fuelled by returning gas from the minor merger event.

\textbf{Key words.} galaxies: evolution – galaxies: individual: NGC 1614 – galaxies: starburst – galaxies: active – radio lines: galaxies – ISM: molecules

1. Introduction

Minor mergers, which are close galaxy interactions where the partners have an unequal mass ratio, constitute the majority of interacting events in the Universe. The gas accretion and nuclear feeding mechanisms of these mergers are different from major mergers (equal-mass interactions, e.g., \cite{Naab2009}). Minor mergers are important for our understanding of galaxy evolution. In particular, they provide insights into how high-redshift spheroidal galaxies evolve into systems at low-redshift, such as local elliptical galaxies, and the formation of galaxy bulges (e.g., \cite{Naab2009} \cite{Weinzirl2009}). In minor mergers, gas introduced into the interacting system by the disturbing companion can generally be found at large radii from the center of the merger remnant \cite{Bournaud2005}. Stellar bars, causing gravitational torques to affect the gas, and/or tidal torques invoked by the disturbing companion, may lead to the transport of the molecular gas along the large-scale dust lanes to the mergers center, with this material acting to fuel both star formation and nuclear accretion (e.g., \cite{Simkin1980} \cite{Scoville1985} \cite{Jogee2006} \cite{Weinzirl2009}). There the gas may form polar rings that can appear as dust lanes when seen edge-on (e.g., \cite{Combes1988} \cite{Shlosman1989}). We have found evidence that gas is funneled along polar rings \cite{Aalto2000} \cite{Aalto2010} \cite{Koenig2013} \cite{Koenig2014}. Tracing this gas is vital to understand the underlying galaxy-evolution and star-formation mechanisms in...
the nucleus. The presence of a circumnuclear ring (\textit{show}s intense nuclear activity and a complex morphology, and is fueled by gas moving in along the dust lanes onto the ring or that the ring is formed at the location of a Lindblad resonance proposed: a “wildfire” scenario (Alonso-Herrero et al. 2001) starburst at its center (\textit{residing} in the ring itself (6–7 Myr, Puxley & Brand 1999; of the nuclear activity originates from a very young starburst continuum (e.g., Olsson et al. 2010; König et al. 2013). Most

this class of mergers.

Spectral lines of molecular isotopologs (isotopic variants) can be used to study the effect of infall, enrichment and gas physical conditions. Elevated line ratios between the \(^{12}\)C and \(^{13}\)C variants of CO have, for example, been proposed to indicate a replenishment of relatively unprocessed disk gas (e.g., Casoli et al. 1992; Henkel & Mauersberger 1993; Taniguchi et al. 1999). However, the ratio cannot be used to infer values on \(^{12}\)C/\(^{13}\)C without taking e-

results on these molecules between upper state \(J = j + 1\) and lower state \(J = j\) that are labeled \(j = \text{i}\). Section[2] describes the observations and the data analysis, in Sect.[3] the results of the observations are presented, and we discuss their implications in Sect.[4].

2. Observations, data reduction and analysis

NGC 1614 was observed with the the Atacama Large Millimeter/submillimeter Array (ALMA) in band 3 (3 mm) as part of Cycle 2 observations of project 2013.1.00991.S (PI: S. König). Here we focus on the data obtained with the ALMA Compact Array (ACA) and the ALMA main array in compact configuration. The ACA observations took place on 2014 June 16 and 30, the ALMA compact configuration observations on 2014 December 4 and 5. The phase center of the observations was located at \(\alpha = 04:34:00.02688\) and \(\delta = -08.34.44.5692\) (J2000). Two tunings were obtained centered on 113.5 GHz and 108.5 GHz, where the redshifted frequencies of the \(^{12}\)CO 1−0 and \(^{13}\)CO 1−0 lines are located. Other lines observed within the ALMA band are \(^{12}\)O 1−0, CN 1−0 and CS 2−1. The 3 mm continuum was reconstructed using line-free channels. We used four spectral windows of 1.875 GHz bandwidth (∼5000 km s\(^{-1}\)) each, with a velocity resolution of ∼5 km s\(^{-1}\), after Hanning smoothing. During the observations, different sources were observed for calibration purposes: Uranus as flux calibrator, J0339-0146 as bandpass calibrator, and J0423-0120 as bandpass and phase calibrator. With baseline lengths of between 8.8 m and 49.0 m, the ACA data are sensitive to scales smaller than ∼38″. The compact configuration main array ALMA data are sensitive to scales smaller than ∼22″ (baselines: 15.0 m – 390 m).

Article number, page 2 of 11
Fig. 2. $^{12}$CO 1−0 emission in NGC 1614. The spectrum of the $^{12}$CO 1−0 emission with a channel width of 10 km s$^{-1}$ is shown on the left, an overlay of the integrated emission contours on top of an HST ACS F435W filter gray-scale image is shown on the right. The integrated intensity map was obtained using uniform weighting. The resulting 1σ sensitivity is $\sim$1.6 mJy beam$^{-1}$, the synthesized beam (see Table 1) is depicted in the lower right corner. The first three contour levels are at 3σ, 13σ, and 23σ. For legibility purposes, the next contour is at 50σ; from there on the subsequent contours are spaced by 50σ until the peak flux is reached. The cross marks the phase center. North is up, east to the left.

For all emission lines, sets of visibilities from ACA and the compact configuration observations were combined by weighting the individual data sets in the $uv$ plane to guarantee a continuous amplitude vs. $uv$-distance distribution. The combined data set was then deconvolved using the “clean” task in CASA, and individual data cubes were created for each observable (continuum and emission lines). The resulting beam sizes and sensitivities are shown in Table 1.

After calibration and imaging within CASA McMullin et al. 2007, both visibility sets were converted into FITS format and imported in the GILDAS/MAPPING for further analysis. All integrated intensity maps in this paper are moment-zero maps. To obtain the $^{12}$CO-to-$^{13}$CO 1−0 map in Fig. 6, we used the integrated intensity maps of the two emission line distributions without a-priori clipping. The resulting maps were smoothed to a common beam at $5'' \times 5''$, and then the ratio map was obtained on a pixel-by-pixel basis. Only pixels with signal-to-noise ratios equal to or higher than 5 in the ratio map were taken into account and are depicted in the resulting image.

3. Results

3.1. 3 mm continuum

The 3 mm continuum (Fig. 1) is centrally peaked at the nucleus of NGC 1614. The total integrated flux recovered from the area enclosed by the the 3σ contours in the uniformly weighted map is $\sim$12.9 mJy. The size and structure of the distribution, however, show more extended features as well. The emission seems to be elongated with a northeast-southwest direction similar to what was observed for $^{12}$CO 1−0 previously Olsson et al. 2010; Sliwa et al. 2014. The continuum emission is clearly associated with the bulk of the $^{12}$CO emission, but also with the dust lanes in the center of NGC 1614. Previously published observations of the 1.3 mm continuum Wilson et al. 2008; König et al. 2013 show a more compact distribution ($\sim$6-7') of the emission, even with comparable spatial resolution. This might be partially due to the excellent continuum sensitivity in our observations compared to previous data sets, but it could also be that the continuum at higher frequencies is more associated with the gas in the molecular ring (König et al. 2013) than the larger-scale molecular gas reservoir (Olsson et al. 2010; Sliwa et al. 2014).

3.2. $^{12}$CO 1−0

The $^{12}$CO 1−0 emission in NGC 1614 is more extended than the 3 mm continuum emission. In addition to the difference in size,

1 http://casa.nrao.edu/

2 http://www.iram.fr/IRAMFR/GILDAS
the $^{12}$CO distribution also shows a significantly different structure than the 3 mm continuum (Fig. 2). Location and general morphology are in agreement with the results of Olsson et al. (2010), Sliwa et al. (2014), and García-Burillo et al. (2015). The gas distribution appears centrally peaked with a significant elongation along a northeast-southwest direction, associated with the dust lanes in the center of NGC 1614. Olsson et al. (2010) found an extent of about $11′′$. Sliwa et al. (2014) about $14′′$. García-Burillo et al. (2015) about $12′′$. In our data the extension is roughly $23′′$ in the northeast-southwest direction. This difference is due to the higher sensitivity and the integration of short-spacing observations in our data set. Additionally, the distribution in Fig. 2 shows features in the molecular gas that were previously unknown. The extension towards the south, for example, consists of low-surface brightness gas that extends into the tidal tails to the south-southwest of the main body of the galaxy. Hints for the feature extending toward the southeast, continuing the direction of the minor nuclear dust lane, can already be detected in Sliwa et al. (2014) and García-Burillo et al. (2015). Our higher-sensitivity, improved uv-coverage observations now clearly confirm their presence. The total interferometric integrated flux enclosed in the $3σ$ contours is $\sim 241$ Jy km s$^{-1}$, which is about a factor of seven times more than in previous observations of Olsson et al. (2010), and a factor of two more than previously observed by Scoville et al. (1989). A comparison to single-dish observations shows that we recover approximately 115% of the flux that has recently been detected by Costagliola et al. (2011).

The spectrum of the $^{12}$CO 1–0 emission (Fig. 2b) shows a double-peak Gaussian with a FWHM line width of $\sim 250$ km s$^{-1}$. The peak flux is at about 1.1 Jy.

3.3. $^{13}$CO 1–0

Figure 3 shows the spectrum and integrated intensity distribution of the $^{12}$CO in NGC 1614. The emission line appears to be double peaked, with its highest flux being $\sim 0.04$ Jy, and an integrated flux of $\sim 6.6$ Jy km s$^{-1}$ at a line width (FWHM) of about $250$ km s$^{-1}$. The recovered flux corresponds to 98% of the total flux detected with single-dish observations (Costagliola et al. 2011). Compared to previous interferometric observations, the sensitivity in our observations is increased by a factor of seven. As a result we recover an integrated flux that is twice as high as in these data (Sliwa et al. 2014). The integrated intensity distribution shows the $^{13}$CO 1–0 emission to be situated in an elongated structure of roughly $12′′$ extending from the northeast of the nucleus of NGC 1614 to the southwest of it. The peak of the distribution, however, is located slightly northwest of the nucleus, where the $^{12}$CO 2–1 emission in the molecular ring connects to the dust lane (Fig. A.1; König et al. 2013). A comparison with the Hubble Space Telescope (HST) image (Fig. 3) shows that the $^{13}$CO emission appears to follow the main high brightness star forming structures at the center of NGC 1614. The image furthermore indicates that the extent of the $^{13}$CO emission does not cover the complete extent of the western dust lane. Instead, it seems that the bulk of the $^{13}$CO 1–0 emission is avoiding the dust lane, in contrast to the $^{12}$CO 1–0 emission (see also Fig. A.2).

3.4. C$^{18}$O 1–0, CN 1–0, and CS 2–1

Other molecular emission lines contained in the observed bandwidths are C$^{18}$O 1–0, CN 1–0, and CS 2–1.

The C$^{18}$O 1–0 emission line was not detected. An upper limit at 3σ amounts to $\sim 0.1$ Jy km s$^{-1}$ within the central $4′′ \times 4′′$. This flux limit is a factor of more than 8.5 lower than what has been obtained from previous single-dish observations (Costagliola et al. 2011).

The CN $N=1$–0 emission is located in a compact, unresolved distribution at the nucleus of NGC 1614 (Fig. 3c). With a peak flux of $\sim 0.03$ Jy and an integrated flux of 7.2 Jy km s$^{-1}$, the J = 3/2–1/2 component is stronger than the J = 1/2–1/2 component (Fig. 3b; peak flux: $-0.02$ Jy, integrated flux: $\sim 3.8$ Jy km s$^{-1}$). The total integrated flux is $\sim 10.3$ Jy km s$^{-1}$. The average FWHM line width amounts to $\sim 250$ km s$^{-1}$. R$_{CN}$, the integrated line ratio between the CN $N = 1$–0, $J = 3/2$–1/2 and $J = 1/2$–1/2 components amounts to $\sim 2$, which indicates that the gas traced by the CN emission in NGC 1614 is optically thin.

The CS 2–1 emission is clearly detected in NGC 1614 (Fig. 3d). Its spatial distribution is compact and centered on the nucleus of the galaxy, following the main high-brightness star-forming structures in the HST image (Fig. 3d). The peak flux in the spectrum is at 7.7 mJy. The integrated flux is found to be roughly 1.3 Jy km s$^{-1}$, at a FWHM line width of $\sim 250$ km s$^{-1}$.

3.5. $^{12}$CO-to-$^{13}$CO 1–0 line ratio

From a detailed comparison of the $^{12}$CO and $^{13}$CO 1–0 emission, the distributions indicate an offset in the emission peak location between the two tracers. The $^{12}$CO peaks exactly at the nucleus of NGC 1614, whereas $^{13}$CO peaks slightly to the northwest of it (an overlay image showing the central $14′′$ can be found in the Appendix in Fig. A.2). Furthermore, the two emission distributions are distinctly different in size and structure. A $^{12}$CO-to-$^{13}$CO 1–0 ($R_{10}$) line ratio map (Fig. 5) shows compelling evidence for this. The $R_{10}$ distribution shows an elongated structure of constant value ($\sim 30$) that coincides with the location of the minor axis dust lane close to the nucleus (Fig. 5b). Moving along this direction toward the dust lane in the west of the nucleus, $R_{10}$ increases to its highest values of 40 to 45 at the outer edge of the western dust lane, where the $^{12}$CO 1–0 is largely absent. Toward the northeastern, eastern, and western edge of the map, the distribution shows more normal values ($R_{10} = 10−15$) associated with the gas in the disk of starburst galaxies.

Sliwa et al. (2014) reported $R_{10}$ similar to our findings. Their values range from about 25 to approximately 40–45. Their line ratio map, however, shows a different distribution compared to our work (Fig. 5) at several locations in NGC 1614: the highest values for $R_{10}$ are found toward the southern part of the circumnuclear molecular ring. $R_{10}$ is slightly lower than that to the west (toward the dust lane). The reason might be that Sliwa et al. (2014) only recovered $\sim 50\%$ of the total flux in their data set, while we essentially recovered 100% of the single dish flux. The authors found the same lower $R_{10}$ toward the northeast and east of the ring, however.

Higher resolution observations are necessary to exactly locate the peak in the $R_{10}$ distribution (König et al., in prep.).

4. Discussion

4.1. Line ratio variations

For the first time we were able to measure the $^{12}$CO-to-$^{13}$CO 1–0 line ratio in the central dust lanes in NGC 1614 (Sect. 3.5). We report an overall high $R_{10}$, with increasing values toward the dust western lane. Studies have been published in other nearby minor merger systems, for example, the Medusa merger (Aalto et al. 2010), which show similarly elevated $R_{10}$. It was suggested
that the elevated line ratios are the result of two effects, either acting alone or combined: 1) changes in the physical conditions in the gas, or 2) abundance effects (e.g., Meier & Turner 2004; Aalto et al. 2010). These effects are discussed further below.

4.1.1. Excitation effects

4.1.1.1 Temperature

In the context of the discussion in this section, we assume that the abundances of $^{13}$CO and $^{12}$CO are constant over the central region of interest. High average gas temperatures, low average gas densities, or exceptionally high velocity dispersions in the molecular clouds could be responsible for elevated line ratios (e.g., Aalto et al. 1995; Meier & Turner 2004). In NGC 1614, the gas with the highest $R_{10}$ ratios is located in the dust lane, away from the bulk of the ongoing star formation. This most likely excludes the notion of high gas temperatures as the cause of the elevated line ratio. An alternative mechanism to elevate $R_{10}$, and the absence of star formation in the dust lane, could be mechanical heating and shears caused by shocks. So far, no indications for shocks in the dust lane in NGC 1614 have been found. $^{13}$CO $-2$–$1$ observations at comparable spatial resolutions (Wilson et al. 2008) indicate an emission distribution similar to what we present for $^{13}$CO $1$–$0$ in this work. Assuming that the elevated $R_{10}$ values are due to the presence of high-density gas, we expect densities of about $3 \times 10^4$ cm$^{-3}$ or more. The result would be that the $^{13}$CO $-2$–$1$ flux is a factor of four or more higher than for $^{12}$CO $1$–$0$. This would have been picked up by the observations of Wilson et al. (2008). Thus, the presence of high-density gas due to shocks can most likely be ruled out as the determining factor for the high line ratios in NGC 1614. Furthermore, observations of dense gas tracers like HCN, HCO$^+$ 4–3 and CO$^+$ 6–5 (Imanishi & Nakanihshi 2013; Siwa et al. 2014) have not yielded a detection of dense gas emission in the dust lane, their emission is solely found in the circumnuclear ring.

4.1.1.2 Density

Change in the gas density is a valid option to cause the observed change in $R_{10}$ in NGC 1614, however. A decrease in the gas density may cause an increase in the line ratio: If the gas in the dust lane is diffuse, that is, in the form of non-selfgravitating clouds, the lower critical density favors the emission of $^{12}$CO $1$–$0$ photons. As a result of the so-called radiative trapping the $^{13}$CO line is still bright at critical densities of $\sim 200$–300 cm$^{-3}$, where $^{13}$CO $1$–$0$ is faint (Meier & Turner 2004). Previous studies of nearby galaxies have suggested that the diffuse gas in the dust lane is due to the funneling of gas along the same, thus gas infall is involved (e.g., Aalto & Hüttemeister 2000). If the infalling gas is the only effect causing the increase of $R_{10}$, the abundance ratio over the central region would need to be well mixed, that is, it should have values more corresponding to what is found for the inner Galactic disk (Meier & Turner 2004). $R_{10}$ around 30 at the center of NGC 1614 places the line ratios for the molecular gas there firmly above this (see also Sect. 3.5, e.g., Aalto et al. 1995; Meier & Turner 2004; Aalto et al. 2010). One possible candidate for a secondary line ratio enhancement mechanism could be a density wave in NGC 1614. The situation in M 51 seems to be a good analogy for what we find in NGC 1614. In M 51, Tosaki et al. (2002) found high $^{12}$CO-to-$^{13}$CO $1$–$0$ ratios in the central and interarm regions. Velocity dispersion observations led them to suggest the presence of streaming motions. The authors thus proposed that streaming motions, caused by density wave activity, led to the accumulation of dense gas located in self-gravitating clouds, as traced by $^{13}$CO $1$–$0$, to be located downstream from the diffuse gas that is traced by $^{12}$CO $1$–$0$. This is exactly what we find in NGC 1614: the $R_{10}$ is high in the dust lane where we suspect the gas to be diffuse. Downstream of this gas, traced by $^{12}$CO $1$–$0$, lies the peak of the $^{13}$CO $1$–$0$ distribution. This is also similar to what has been proposed for the Medusa merger (Aalto et al. 2010).

4.1.2. Abundance effects

4.1.2.1 $^{12}$C/$^{13}$C

The $^{12}$CO-to-$^{13}$CO $1$–$0$ intensity line ratio map shows values of about 30 toward the nucleus of NGC 1614 (see Sect. 4.1.1), which corresponds to line ratios found predominantly for warm, turbulent, high-pressure gas in the centers of luminous merging galaxies (e.g., Aalto et al. 1995; Glenn & Hunter 2001). From the discussion of the excitation effects on the line ratios in Sect. 4.1.1 we conclude that diffuse gas in the dust lane under the influence of density wave activity can partially explain elevated values for $R_{10}$. To increase the $^{12}$CO-to-$^{13}$CO $1$–$0$ to a level as we find in NGC 1614 an additional factor has to be taken into account to explain the enrichment of $^{13}$CO, which also causes the relative deficiency of C$^{18}$O. This is the effect of changing abundances. Casoli et al. (1992) suggested that $R_{10}$ could change depending on the $^{12}$CO/$^{13}$CO abundance ratio, $[^{12}$CO]/$[^{13}$CO], when low-metallicity gas was transported from the outskirts of a merger to its center. The starburst would then contribute to enrich the infalling metal-poor gas in $^{13}$C (e.g., Rupke et al. 2008; Henkel et al. 2010). We assume the $^{12}$CO $1$–$0$ line transition to be optically thick ($T \approx 1$), that the $^{12}$CO and $^{13}$CO emission trace the same gas and also that the excitation temperatures for the two are comparable. This would mean that $[^{12}$CO]/$[^{13}$CO] would be roughly 90, which is a typical value for gas farther out in the Galactic disk (e.g., Henkel et al. 1985; Wilson & Rood 1994; Wouterloot & Brand 1996; Henkel et al. 2014), and thus points to the presence of infalling, chemically less processed gas.

4.1.2.2 $^{16}$O/$^{18}$O

Using the C$^{18}$O $1$–$0$ integrated intensity upper limit in the central $4''$×$4''$, the $^{12}$C$^{16}$O-to-$^{12}$C$^{18}$O $1$–$0$ line ratio results in a lower limit of $\sim 0.35$. The resulting abundance ratio is $[^{12}$CO]/$[^{13}$CO] $\approx 900$. Values found for the Galactic center are $\sim 250$, for the solar neighborhood typical values are about 500 (e.g., Wilson & Matteucci 1992). The $[^{12}$CO]/$[^{13}$CO] ratio is significantly higher in NGC 1614 than in the LIRG Wz 049.057 (Falstad et al. 2013), but comparable to what has been found for another LIRG, NGC 4418, (González-Alfonso et al. 2012). It is also comparable to values found in the merger Arp 299 (Falstad et al., in prep.). Interestingly, both Arp 299 and NGC 4418 have molecular gas inflows (Falstad et al. in prep.; Costagliola et al. 2013). Arp 299 also hosts an efficient starburst (e.g., Bondi et al. 2012, and references therein) – just like NGC 1614. Considering that this result for NGC 1614 is only a lower limit to $[^{12}$CO]/$[^{13}$CO], and also taking the high $^{12}$CO-to-$^{18}$C$^{18}$O $1$–$0$ integrated intensity line ratio in the central $4''$×$4''$ into account ($\sim 0.3$), $^{18}$O $1$–$0$ seems very deficient in comparison to $^{12}$CO $1$–$0$, but especially with respect to $^{13}$CO $1$–$0$. C$^{18}$O is thought to come from short-lived massive stars early during

\[3\] For more details see Sect. B
a starburst event (e.g., Prantzos et al. 1996; Meier & Turner 2004), whereas 13 CO 1–0 is predicted to be produced later on in intermediate-mass stars (e.g., Meier & Turner 2004 and references therein). An explanation for this deficiency in the center of NGC 1614 could be that the mixing of the infalling, chemically unprocessed gas with the prevailing gas is not efficient. Although this could also be an effect of the size of the beam in the observations - if the unprocessed infalling gas is located inside the same beam as the prevailing nuclear gas a dilution of the separate signals could occur. This dilemma will be solved by higher resolution observations of the same set of molecular tracers.

Taking the findings in Sect. 4.1.1 and this section into account, we propose that the increase in the 12 CO-to-13 CO ratio in NGC 1614 is caused by the diffuse gas in the dust lane and density wave activity, in combination with enrichment of 13 CO due to infalling metal-poor gas from farther out in the galactic disk. However, a definitive answer to whether a change in the temperature of the gas also has an influence can only be obtained together with sensitivity-matched observations of the 12 CO and 13 CO 2–1 lines.

4.2. NGC 1614 - the big picture?

In this section, we now collate our results together with what has been previously reported on what is going on in NGC 1614. A cartoon representation of the proposed scenario is depicted in Fig. 7.

In 2001, a starburst ring was discovered at the nucleus of NGC 1614 by Alonso-Herrero et al. Its presence was confirmed in a number of other tracers (e.g., Olsson et al. 2010; Väisänen et al. 2012), Alonso-Herrero et al. (2001) suggested that the ring was formed as the result of an outward progressing starburst event that has already consumed most of the gas at its center. The ring also has a molecular component (König et al. 2013; Sliwa et al. 2014; Xu et al. 2015). As a result, it was suggested that the ring is situated at the location of crowded orbits in the merger potential where it is replenished by gas coming in along the dust lane (König et al. 2013; Sliwa et al. 2014). The 12 CO 1–0 (Olsson et al. 2010; Sliwa et al. 2014; García-Burillo et al. 2015, 2–1 (König et al. 2013) and 13 CO 1–0 line transitions trace the low-to-intermediate surface brightness gas that shows how the starburst ring is connected to the large-scale molecular gas reservoir: diffuse gas in the form of unbound giant molecular clouds (GMCs) could be funneled along the dust lane from the molecular gas reservoir at larger scales (seen in 12 CO 1–0) toward the nucleus. During this process, the gas may be hit by a density wave. The resulting shocks could cause the gas density to increase and the molecular clouds to become self-gravitating (as traced by 13 CO 1–0). In this scenario, the molecular clouds are trapped at the connection between the dust lane and the ring, “the umbilical cord” (described by König et al. 2013), inside the mergers potential through crowding processes, for instance. This could lead to collisional coagulation of the GMCs into larger-sized giant molecular associations (GMAs, traced by, e.g., 12 CO 2–1) that then possibly migrate onto the circumnuclear ring. In this way, the nuclear gas reservoir can be constantly replenished. The cloud-cloud interactions could also trigger the onset of star formation in the ring (Scoville et al. 1986; Tan 2000): the high-density gas, such as HCN and HCO+(e.g., Imanishi & Nakaniishi 2013; Sliwa et al. 2014; Xu et al. 2015), is exclusively associated with the star formation itself.

Whether the ring is indeed caused by a wildfire expanding into the surrounding molecular medium or if is solely formed at the location of the resonance in the merger potential is still under discussion. Solving this argument will require further studies: Resolution- and sensitivity-matched 12 CO and 13 CO 2–1 observations will greatly improve our ability to determine whether the presence of non-selfgravitating gas in the dust lane or a change in the temperature of the gas is the cause of the extreme line ratios in NGC 1614. Higher resolution 12 CO 1–0 observations at high sensitivity are needed to search for indicators of possible streaming motions between the large-scale and small-scale molecular gas reservoirs to verify the funneling of gas along the dust lanes toward the circumnuclear ring. They would also allow us to study the possible connection between the CO 1–0 and the CO 2–1 gas reservoirs in more detail, thus allowing to collect evidence in favor or against the competing scenarios proposed for the formation of the circumnuclear ring.

4.2.1. Implications for high-redshift studies of mergers

We would also like to stress that our results emphasize the need to be cautious which tracers of the molecular gas to best use to determine star formation capabilities, also for studies at high redshifts. We have especially shown in this paper that the 12 CO 1–0 emission is not necessarily a tracer of the overall content of the molecular gas that is capable to partake in star formation because a high percentage of it might be in the form of diffuse molecular gas. Additional observations at higher-J CO transitions are necessary to conclude on this. Furthermore, C18O should be used with caution to determine the age of the starburst activity in galaxies with proven gas infall. The mixing of the infalling gas with the prevailing gaseous materials might falsify the age determination to a large degree.

5. Summary

In summary, with the ALMA observations presented here, we showed that the nearby starburst galaxy NGC 1614 harbors large reservoirs of molecular gas traced by 12 CO and 13 CO 1–0. The 12 CO emission is widely distributed throughout the galaxy and has a strong connection to the dust lanes, whereas the 13 CO emission is much more compact and seems to avoid them. This possibly indicates non-selfgravitating, diffuse gas in the dust lane that originates from farther out in the galaxy disk. The 13 CO 1–0 emission distribution is most likely a result of the effect of the progression of density waves on the galaxies molecular medium. In addition to 12 CO and 13 CO 1–0, other molecular gas tracers such as CN 1–0 and CS 2–1 are present in NGC 1614. For C18O only an upper limit was found.

Fig. 3. Spectrum of the $^{13}$CO 1−0 emission in NGC 1614 (channel width: 10 km s$^{-1}$, left), and overlay of the integrated emission contours on top of an HST ACS F435W filter gray-scale image (right). The contours in the map obtained from natural weighting start at 4σ and are spaced in steps of 3σ. The 1σ sensitivity here is $\sim$1.4 mJy beam$^{-1}$. The beam (see Table 1) is depicted in the bottom right corner. The cross marks the phase center. North is up, east to the left.

Fig. 4. Spectrum of the CN 1−0 emission in NGC 1614 (left), and overlay of the integrated emission on top of an HST ACS F435W filter gray-scale image (right). In the spectrum (channel width: 10 km s$^{-1}$) the hyperfine-structure components of CN 1−0 are indicated in green. The blue line represents the convolution of the CN hyperfine structure with a Gaussian profile. This indicates that the gas traced by the CN 1−0 emission in NGC 1614 is optically thin. The integrated intensity map was obtained using uniform weighting. The resulting sensitivity is $\sim$1.3 mJy beam$^{-1}$, the resulting beam is depicted in the bottom right corner. The contour levels of the integrated emission start at 5σ and are spaced in steps of 5σ. The beam (see also Table 1) is depicted in the lower right corner. The cross marks the phase center. North is up, east to the left.
Fig. 5. Spectrum of the CS 2–1 emission in NGC 1614 (left), and overlay of the integrated emission on top of an HST ACS F435W filter gray-scale image (right). The channels in the spectrum were binned to 30 km s\(^{-1}\). The contours of the integrated emission in the naturally weighted map start at 3.5\(\sigma\) and are spaced in steps of 3\(\sigma\) (1\(\sigma\) = 0.8 mJy beam\(^{-1}\)). The beam (see also Table 1) is depicted. The cross marks the phase center. North is up, east to the left.

Fig. 6. \(^{12}\text{CO}\)-to-\(^{13}\text{CO}\) integrated intensity line ratio (\(R\)) map (left) and overlay of the same in contours on top of an HST ACS F435W filter gray-scale image (right). The ratio decreases from about 40–45 at the northwestern edge down to \(\sim\)30 along the nuclear dust lane, and \(\sim\)10–20 at the northeastern, eastern, and western edges. \(R\) seems to be quite constant along the nuclear dust lane until the ratio steeply increases toward the dust lane in the west. North is up, east to the left, and the beam is shown in the lower right corner of each map. The cross marks the position of the phase center.
A high percentage of the $^{12}$CO $1-0$ emission (hatched red) is associated with the dust lane. The gas in the dust lane is in the form of diffuse gas. The $^{13}$CO $1-0$ emitting gas is not fully distributed throughout the dust lane (hatched gray). Its emission peak (blue star) is located in the "umbilical cord", the connection between the molecular gas in the circumnuclear ring, traced by $^{12}$CO $2-1$ emission (crosshatch pattern, König et al. 2013), and the dust lane. The diffuse gas is being transported along the dust lane in the form of unbound molecular clouds (GMCs). The interaction with density waves (red arrows) causes the gas in the clouds to become self-gravitating. In the umbilical cord, crowding processes in the merger potential occur and the GMCs form GMAs through collisional coagulation. These larger associations are then transported further onto the circumnuclear ring and star formation may be triggered.
Appendix A: Comparison overlays of $^{12}\text{CO}\,1−0$, $2−1$ and $^{13}\text{CO}\,1−0$ emission distributions

Figures A.1 and A.2 show overlays of $^{12}\text{CO}\,1−0$, $2−1$, and $^{13}\text{CO}\,1−0$ that might be useful for a closer look at the detailed structure of NGC 1614. The observations used here are presented in this work or have been previously published.

Fig. A.1. Comparison of high-resolution $^{12}\text{CO}\,2−1$ observations with the SMA (black contours, König et al. 2013) to the ALMA $^{13}\text{CO}\,1−0$ emission presented in this work (color scale). Note how the $^{13}\text{CO}\,1−0$ emission peaks exactly at the location of the connection between the molecular ring and the dust lane (grey contours, see also Figs. 1a & 3 in König et al. 2013). The $^{12}\text{CO}\,2−1$ contours start at $4\sigma$ and are spaced in steps of $4\sigma$ ($1\sigma = 6.16$ mJy beam$^{-1}$). North is up, east to the left, and the beams are shown in the lower right corner of the image. The cross marks the position of the phase center of the observations.

Appendix B: Conversion of line ratios into abundance ratios

To study the effects of changes in abundance ratios vs. the effects of different excitation mechanisms, we used the $^{12}\text{CO}$-to-$^{13}\text{CO}\,1−0$ ratio distribution in NGC 1614 to derive the abundance ratio ($^{12}\text{CO}/^{13}\text{CO}$). While $r(^{12}\text{CO}\,1−0)$ in galaxy disks (i.e., an ensemble of GMCs) may well exceed unity, there is mounting evidence that the emitting CO surfaces in galaxy centers have moderate optical depths (e.g., Aalto et al. 1995; Downes & Solomon 1998; Israel 2009), this is also true for the Galactic center (e.g., Polk et al. 1988; Dahmen et al. 1998). Since a $\tau = 1$ surface would have the optical combination of filling factor and brightness temperature it is a reasonable assumption that much of the CO emission would be emerging from these surfaces. Thus, we use as a first-order approximation of the optical depth of $\tau = 1$ in our data as a starting point to study the physical gas properties and mechanisms with a simple model. This is justified for the molecular gas in NGC 1614 based on several pieces of evidence: 1) In the dust lane the gas density is low: Studies associate high-density gas tracers exclusively with the circumnuclear ring (e.g., Imanishi & Nakanishi 2013; Shiwa et al. 2014; Xu et al. 2015); thus, the brightness temperature measured in the dust lane suggests that the gas has a $\tau$ of $\geq 1$. If the emission is optically thin in a cool, low-density environment, its brightness temperature is $< 1$ K at this resolution. 2) In

Fig. A.2. Overlay of the $^{13}\text{CO}\,1−0$ emission observed with ALMA (gray contours) on top of the $^{12}\text{CO}\,1−0$ emission observed with ALMA (color scale). Note how the bulk of the $^{12}\text{CO}\,1−0$ emission is located outside the dust lane to the west of the nucleus (white contours). Moreover, the $^{13}\text{CO}\,1−0$ located in the dust lane does not cover its full extent. The $^{13}\text{CO}\,1−0$ contours are the same as in Fig. 3b. North is up, east to the left, and the beams are shown in the lower right corner of the image. The cross marks the position of the phase center of the observations.
