Linear Convergence of Distributed Mirror Descent with Integral Feedback for Strongly Convex Problems

Youbang Sun
Shahin Shahrampour

Abstract

Distributed optimization often requires finding the minimum of a global objective function written as a sum of local functions. A group of agents work collectively to minimize the global function. We study a continuous-time decentralized mirror descent algorithm that uses purely local gradient information to converge to the global optimal solution. The algorithm enforces consensus among agents using the idea of integral feedback. Recently, Sun and Shahrampour (2020) studied the asymptotic convergence of this algorithm for when the global function is strongly convex but local functions are convex. Using control theory tools, in this work, we prove that the algorithm indeed achieves (local) exponential convergence. We also provide a numerical experiment on a real dataset as a validation of the convergence speed of our algorithm.

Keywords: Mirror Descent, Distributed Optimization, Integral Feedback, Continuous-time Dynamics

1. Introduction

Distributed gradient-based optimization is well-studied in the literature. Generally, the problem is to find the optimal solution for a global objective function that is a sum of local cost functions assigned to various agents. Each agent only has limited knowledge of the global problem, and the agents must work collectively to reach consensus around the optimum for the global objective function. Distributed optimization has applications in distributed resource allocation Chavez et al. (1997), distributed sensor localization Khan et al. (2009), distributed cooperative control Qu (2009), social learning Shahrampour et al. (2015), and beyond.

Naturally, one of the most fundamental questions in distributed optimization is that whether a distributed algorithm is able to match the performance of its centralized counterpart. The basic idea of gradient descent with local averaging has proven to be a simple yet powerful approach. The seminal work of Nedic and Ozdaglar (2009) is a prominent point in case, which shows this approach converges for convex problems using a diminishing step-size sequence, which decreases the influence of local gradients and allows all agents to reach consensus. However, as soon as assumptions like smoothness and/or strong convexity come into play, a diminishing step-size may no longer be optimal in centralized optimization, thereby being a sub-optimal choice for decentralized algorithms as well.

A number of works proposed gradient tracking, that uses an additional term to ensure consensus with non-decreasing step-sizes. This line of work includes EXTRA Shi et al. (2015) and DEXTRA Xi and Khan (2017), where we can observe decentralized performances on par with their respective centralized problems. In continuous-time distributed optimization, another approach, termed inte-
gral feedback, has been used in the literature in a similar spirit. The integral feedback introduces another variable to account for differences between agents and helps the network reach consensus. Examples of recent works adopting this approach include Gharesifard and Cortés (2013); Kia et al. (2015); Zeng et al. (2017); Yang et al. (2016).

However, most of the recent works in distributed gradient-based optimization have focused on gradient descent. Although effective, gradient descent sometimes cannot yield desirable results by not exploiting the geometry of the problem. Mirror descent Nemirovsky and Yudin (1983), on the other hand, is widely used in large-scale optimization problems. Mirror descent replaces the Euclidean distance in gradient descent with Bregman divergence as the regularizer, and it can be viewed as a more general version of gradient descent. For some of high-dimensional optimization problems, mirror descent can provide significantly faster convergence rates compared to gradient descent Ben-Tal et al. (2001).

Motivated by the generality of mirror descent, in this work we focus on distributed mirror descent (DMD). Most of prior work on DMD is in discrete time (see e.g., Shahrampour and Jadbabaie (2018); Yuan et al. (2018); Rabbat (2015); Li et al. (2016); Doan et al. (2019)). With the exception of Rabbat (2015), the works above either use diminishing step-size sequence or multi-communications per round in order to reach consensus. For the same reasons mentioned for gradient descent, a diminishing step-size would not be optimal for strongly convex problems, resulting in slower convergence compared to centralized methods. In this work, we study continuous-time DMD with integral feedback, recently proposed in Sun and Shahrampour (2020). The authors focused on a setup where the global objective is strongly convex but the local functions are convex, and they provided asymptotic convergence analysis. In the current work, we use dynamical systems tools (Lyapunov’s indirect method) to prove the local exponential convergence of DMD with integral feedback. We also test our algorithm on a real data-set to show that the proposed algorithm indeed converges exponentially fast (or linearly in log-scale).

We remark that DMD in continuous time has also been studied prior to this work, mostly by focusing on reduction of noise variance in stochastic optimization Borovykh et al. (2020); Raginsky and Bouvrie (2012). Yu and Açıkmeşe (2020) also motivate mirror descent using RLC circuits and utilize derivative and integration in the algorithm. The distinction between Yu and Açıkmeşe (2020) and the current work includes different assumptions on the objective functions, which yields different convergence results.

2. Problem Formulation

**Notation:** We let \([n]\) denote the set \(\{1, 2, 3, \ldots, n\}\) for any integer \(n\). \(x^\top\) (and \(A^\top\)) denotes transpose of vector \(x\) (and matrix \(A\)), respectively. \(I_d\) represents identity matrix of size \(d \times d\). We let \(1_d\) denote \(d\)-dimensional vector of all ones. \(\langle x, y \rangle\) denotes the standard inner product between \(x\) and \(y\) and \(\|x\| = \sqrt{\langle x, x \rangle}\) is the Euclidean norm of vector \(x\). \(A \otimes B\) represents the Kronecker product of matrices \(A\) and \(B\). The \(i\)-th element of the vector \(x\) is denoted by \([x]_i\), and the \(ij\)-th element of the matrix \(A\) is denoted by \([A]_{ij}\). We let \(\text{det}(A)\) denote the determinant of matrix \(A\) and use \(\text{col}\{v_1, \ldots, v_n\}\) to denote the vector that stacks all vectors \(v_i\) for \(i \in [n]\). We use \(\text{diag}\{a_1, \ldots, a_n\}\) to represent an \(n \times n\) diagonal matrix that has the scalar \(a_i\) in its \(i\)-th diagonal element. We use \(\text{Re}[\cdot]\) to denote the real part of a complex number. We use \(0\) to represent the null vector and the null matrix when it is clear from the context.
2.1. Distributed Optimization

Distributed convex optimization consists of minimizing an objective function \( F : \mathcal{X} \to \mathbb{R} \) defined on a compact and convex set \( \mathcal{X} \subset \mathbb{R}^d \). \( F \) is written as a sum of local cost functions, denoted by \( f_i : \mathcal{X} \to \mathbb{R} \) for \( i \in [n] \), and the cost function \( f_i \) is associated with agent \( i \). The minimization task is as follows

\[
\min_{x \in \mathcal{X}} F(x) = \sum_{i=1}^{n} f_i(x). \tag{1}
\]

In a distributed optimization setup, agents only have the information about their associated local functions, and the network of agents relies on communication between agents in order to find the solution to the global task presented in (1). We now introduce some assumptions on the local and global functions.

**Assumption 1** For any agent \( i \in [n] \) in the network, we assume that the local cost function \( f_i : \mathcal{X} \to \mathbb{R} \) is convex and differentiable.

From this assumption, we can immediately get that the global function \( F \) is also convex and differentiable, but we impose an additional assumption on the global cost function as follows.

**Assumption 2** The global function \( F : \mathcal{X} \to \mathbb{R} \) is strongly convex. There exists a unique minimizer for \( F \) and the optimal value denoted by \( F^* = F(x^*) \) exists. The gradients of local functions \( \nabla f_i(x) \) are locally continuously differentiable around \( x^* \).

2.2. Network Settings

The agents form a network, modeled by a simple undirected graph \( G = (V, E) \), where the agents are denoted by nodes \( V = [n] \) and the connection between two agents \( i \) and \( j \) is captured by the edge \( \{i, j\} \in E \). The neighborhood of agent \( i \) is denoted by \( N_i \triangleq \{ j \in V : \{i, j\} \in E \} \). The agents work collectively to find the optimum of the global cost function, which is the sum of all local cost functions.

**Assumption 3** The graph \( G \) is connected, i.e., there exists a path between any two distinct agents \( i, j \in V \). The graph Laplacian is denoted by \( \mathcal{L} \in \mathbb{R}^{n \times n} \).

The connectivity assumption implies that \( \mathcal{L} \) has a unique null eigenvalue. That is, \( \mathcal{L} \mathbbm{1}_n = 0 \), and \( \mathbbm{1}_n \) is the only direction (eigenvector) recovering the zero eigenvalue.

2.3. Mirror Descent

We now provide a brief introduction of centralized mirror descent algorithm and explain the transition from discrete mirror descent (as mentioned in Nemirovsky and Yudin (1983) ) to a continuous-time setup. Later, in Section 2.4 we derive the distributed mirror descent updates in continuous time.

In gradient descent method, each iterate can be seen as an optimization problem on a simplified model, constructed by a first order approximation of a function plus a Euclidean regularizer. Mirror descent replaces the Euclidean regularizer with Bregman divergence. Bregman divergence is defined with respect to a distance generating function (DGF) \( \phi : \mathcal{X} \to \mathbb{R} \), as follows

\[
D_\phi(x, x') \triangleq \phi(x) - \phi(x') - \langle \nabla \phi(x'), x - x' \rangle. \tag{2}
\]
In discrete time, the mirror descent algorithm with learning rate $\eta$ is written as

$$x^{(k+1)} = \text{argmin}_{x \in \mathcal{X}} \left\{ F(x^{(k)}) + \eta \nabla F(x^{(k)})^\top (x - x^{(k)}) + \mathcal{D}_\phi(x, x^{(k)}) \right\}. \tag{3}$$

Bregman divergence is regarded as a more general version of the Euclidean regularizer. When using the Euclidean distance as the Bregman divergence (i.e., $\mathcal{D}_\phi(x, x^{(k)}) = \frac{1}{2} \|x - x^{(k)}\|^2$) we recover gradient descent. Hence, mirror descent is seen as a more general version of gradient descent.

**Assumption 4** The distance generating function $\phi$ is closed, differentiable and $\mu_\phi$-strongly convex.

**Assumption 5** The Hessian of distance generating function, $\nabla^2 \phi$, is locally continuously differentiable around the neighborhood of $x^*$ (the minimizer of $F$).

The two assumptions above on $\phi$ are satisfied by some of the commonly used Bregman divergences, such as $\phi(x) = \frac{1}{2} \|x\|^2$, DGF of the Euclidean distance, and the negative entropy function $\phi(x) = \sum_{j=1}^d [x_j] \log([x_j])$, DGF of the Kullback–Leibler divergence.

Now, we introduce an equivalent form of the update above for more convenient analysis. This equivalent form is based on the convex conjugate (also known as Fenchel dual) of function $\phi$, which is denoted by $\phi^*$ and defined as follows

$$\phi^*(z) \triangleq \sup_{x \in \mathcal{X}} \{ \langle x, z \rangle - \phi(x) \}.$$  

From the definition, we can derive the the subsequent relationship,

$$z = \nabla \phi(x) \iff x = \nabla \phi^*(z).$$

This means $\nabla \phi^*$ will map the range of $z$ back to $\mathcal{X}$. Assumption 4 on the DGF $\phi$ guarantees the $\mu_\phi^{-1}$-smoothness property on $\phi^*$ (see e.g., Hiriart-Urruty and Lemaréchal (2012)). Using the definition of $\phi^*$, the update (3) can be rewritten in the following equivalent form

$$z^{(k+1)} = z^{(k)} - \eta \nabla F(x^{(k)}),$$

$$x^{(k+1)} = \nabla \phi^*(z^{(k+1)}). \tag{4}$$

Then, the continuous-time update can be obtained by setting $\eta$ infinitesimally small as follows

$$\dot{z} = -\nabla F(x),$$

$$x = \nabla \phi^*(z), \tag{5}$$

$x(0) = x_0, z(0) = z_0$ with $x_0 = \nabla \phi^*(z_0)$,

This setup was studied in Krichene et al. (2015).

### 2.4. Distributed Mirror Descent with Integral Feedback

In this section, we introduce the distributed algorithm for mirror descent shown in (5). Our end goal is to have all agents converge to the global optimum in (1) and reach consensus. Motivated by
Gharesifard and Cortés (2013); Kia et al. (2015), we use integral feedback to get

\[ \dot{z}_i = -\nabla f_i(x_i) + \sum_{j \in \mathcal{N}_i} (x_j - x_i) + \int_0^t \sum_{j \in \mathcal{N}_i} (x_j - x_i) \]

\[ x_i = \nabla \phi^* (z_i), \]  

(6)

with \( x_i(0) = x_{i0} \), \( z_i(0) = z_{i0} \), and \( x_{i0} = \nabla \phi^* (z_{i0}) \).

The algorithm only utilizes gradient information of the local costs. The first equation updates the dual variable \( z_i \) using gradient information, a consensus term, and the integral feedback. Then, the second equation updates the primal variable by mirroring the dual variable back with function \( \phi^* \).

For convenience, we stack vectors from all agents and define the following notation,

\[ \mathbf{L} \triangleq \mathcal{L} \otimes I_d \]

\[ \mathbf{x} \triangleq \text{col}\{x_1, x_2, \ldots, x_n\} \]

\[ \mathbf{z} \triangleq \text{col}\{z_1, z_2, \ldots, z_n\}, \]  

\[ \nabla \phi^* (\mathbf{z}) \triangleq \text{col}\{\nabla \phi^* (z_1), \nabla \phi^* (z_2), \ldots, \nabla \phi^* (z_n)\} \]

\[ \nabla \mathbf{f} (\mathbf{x}) \triangleq \text{col}\{\nabla f_1(x_1), \nabla f_2(x_2), \ldots, \nabla f_n(x_n)\}. \]  

(7)

Additionally, we introduce a variable \( \mathbf{y} \) to replace the integral. Then, the dynamical system (6) can be written using the newly defined notations,

\[ \dot{\mathbf{z}} = -(\nabla \mathbf{f} (\mathbf{x}) + \mathbf{L} \mathbf{x} + \mathbf{y}), \]

\[ \dot{\mathbf{y}} = \mathbf{L} \mathbf{x}, \]

\[ \mathbf{x} = \nabla \phi^* (\mathbf{z}), \]  

(8)

where \( \mathbf{y} \in \mathbb{R}^{nd} \) and \( \mathbf{y}(0) = 0 \).

3. Main Results

In this section, we provide the convergence results of (8). In particular, we prove that under our assumptions, all agents in the network will converge exponentially fast to the global minimum of \( F \) in (1). In a previous work, the authors showed that under a subset of assumptions, the algorithm will asymptotically converge to the global optimum (without providing the rate).

**Theorem 1** [Sun and Shahrampour (2020)] Given Assumptions 1-4, for any starting point \( x_i(0) = x_{i0}, z_i(0) = z_{i0} \) with \( x_{i0} = \nabla \phi^* (z_{i0}) \), the distributed mirror descent algorithm with integral feedback proposed in (6) will converge to the global optimum asymptotically, i.e., \( \lim_{t \to \infty} x_i(t) = x^* \) for any \( i \in [n] \).

The proof of this theorem can be found in Sun and Shahrampour (2020), where it is also shown that agents reach consensus at the global optimal point, which is the unique equilibrium of the dynamical system (8). The equilibrium point for \( \mathbf{x}, \mathbf{y}, \mathbf{z} \) is denoted by

\[ \mathbf{x}^* = \mathbbm{1}_n \otimes x^*, \quad \mathbf{y}^* = -\nabla \mathbf{f} (\mathbf{x}^*), \quad \mathbf{z}^* = \mathbbm{1}_n \otimes z^* = \mathbbm{1}_n \otimes \nabla \phi (x^*). \]
3.1. Coordinate Transformation

We use the change of variables in Sun and Shahrampour (2020) for further analysis. Let $S = L^{\frac{1}{2}}$, and recall that $L = \mathcal{L} \otimes I_d$ is a symmetric positive semi-definite matrix. We then introduce a new variable $w(t) = S \int_0^t x(\tau) d\tau$. From (8) it is easy to show that $y = Sw$. We then center the variables by moving the system’s equilibrium to the origin as follows

$$\tilde{x} \triangleq x - x^*, \quad \tilde{y} \triangleq y - y^*, \quad \tilde{w} \triangleq w - w^*, \quad \tilde{z} \triangleq z - z^*. \quad (9)$$

The first two equations in (8) can be rewritten as

$$\dot{\tilde{z}} = -(\nabla f(\tilde{x} + x^*) - \nabla f(x^*)) - L\tilde{x} - Sw,$$
$$\dot{\tilde{w}} = S\tilde{x}, \quad (10)$$

Next, we perform a dimension reduction on variable $\tilde{w}$. Define $r \triangleq \frac{1}{\sqrt{n}} I_n$ and let $L = Q \Lambda Q^T$, where $\Lambda = \text{diag}\{0, \lambda_1, ..., \lambda_{n-1}\}$. From Assumption 3 it is clear that $r$ is the first column of $Q$. We then define $R \in \mathbb{R}^{n \times (n-1)}$ such that $Q = [r, R]$. The following relationships follow subsequently

$$r^T R = 0, \quad R^T R = I_{n-1}, \quad RR^T = I_n - \frac{1}{n} 1_n 1_n^T, \quad r^T L r = 0, \quad R^T LR > 0. \quad (11)$$

Now, let

$$r \triangleq r \otimes I_d, \quad R \triangleq R \otimes I_d, \quad Q \triangleq Q \otimes I_d, \quad (12)$$

and define new vectors by the following transformations from $\tilde{w}$,

$$W \triangleq Q^T \tilde{w} = \begin{bmatrix} r^T \\ R^T \end{bmatrix} \tilde{w} = \begin{bmatrix} r^T \tilde{w} \\ R^T \tilde{w} \end{bmatrix} = \begin{bmatrix} W_1 \\ W_2 \end{bmatrix}. \quad \text{(13)}$$

Note that for $W_1$, from (10) we can derive that

$$W_1 = r^T \tilde{w} = r^T S\tilde{x} = 0, \quad W_1(0) = -r^T w^* = 0.$$

Therefore $W_1 \equiv 0$ for all time $t$, and the system variable can be represented by $W_2$ only. $\tilde{w} = [r \ R] W = rW_1 + RW_2 = RW_2$.

Furthermore, we replace variable $z$ with $x$. Since $z = \nabla \phi(x)$, we have

$$\dot{\tilde{z}} = \frac{d}{dt}(z - z^*) = \nabla^2 \phi(x) \dot{x}. \quad \text{(13)}$$

Assumption 4 implies that $\nabla^2 \phi(x)$ is positive definite and therefore invertible. Now, we can rewrite the system in (10) using only variables $\tilde{x}$ and $W_2$ as follows

$$\dot{\tilde{x}} = -\nabla^2 \phi(\tilde{x} + x^*)^{-1}(\nabla f(\tilde{x} + x^*) - \nabla f(x^*) + L\tilde{x} + SRW_2), \quad W_2 = R^T S\tilde{x}, \quad \text{(13)}$$

Thus, the (exponential) stability of (8) can be analyzed using the (exponential) stability of (13).
3.2. Exponential Convergence

With the system transformation in place, we can discuss the convergence and stability of distributed mirror descent (with integral feedback) in the following theorem.

**Theorem 2** (Main Result) Given Assumptions 1-5, the origin is a locally exponentially stable equilibrium of (8) and (13).

**Proof** If we linearize the system (13) at the origin, using the notation \( \nabla^2 \phi(\tilde{x} + x^*)^{-1}|_{\tilde{x} = 0} = D \), \( \nabla^2 f(\tilde{x} + x^*)|_{\tilde{x} = 0} = H \), the linearized version of (13) is

\[
\begin{bmatrix}
\dot{\tilde{x}} \\
\dot{W}_2
\end{bmatrix} = -M \begin{bmatrix}
\tilde{x} \\
W_2
\end{bmatrix}, \quad \text{where} \quad M \triangleq \begin{bmatrix}
D(H + L) & DSR \\
-R^\top S & 0
\end{bmatrix}.
\] (14)

We denote by \( \lambda_1, ..., \lambda_{(2n-1)d} \) the eigenvalues of the linearized system matrix \( M \) in (14). Based on Lemma 4, \( \Re \{ \lambda \} > 0 \) for all eigenvalues. Lemma 4 and its proof are provided later in the paper.

Now, from Theorem 3.2 in Khalil (2014), since \( \Re \{ \lambda \} > 0 \), the equilibrium of system (13), as well as the equilibrium of system (8) given by Theorem 1, are both locally exponentially stable. This means there exists \( \delta > 0 \) such that for any \( \| \text{col} \{ x, y, z \} - \text{col} \{ x^*, y^*, z^* \} \| \leq \delta \), the system state variables converge to the equilibrium (global optimal solution) exponentially fast.

Recall from Theorem 1 that the system (8) also exhibits global asymptotic convergence to the equilibrium. Then, for any starting point for \( \text{col} \{ x, y, z \} \), the state variables can converge to a neighborhood of radius \( \delta \) of equilibrium in a finite time \( T(\delta) \). Combined with the exponential convergence rate within the ball, this means that (after a finite time), the system exhibits exponential convergence to the global optimal solution.

We now provide the following two lemmas used in the proof of Theorem 2.

**Lemma 3** Given Assumptions 1-3, the matrix \( (H + L) \) is positive definite.

**Proof** First, \( (H + L) \) is symmetric since both \( H \) and \( L \) are symmetric. For any non-zero vector \( v \in \mathbb{R}^{nd} \), from Assumptions 1 and 3, we know that

\[
v^\top Hv \geq 0, v^\top Lv \geq 0 \implies v^\top (H + L)v = v^\top Hv + v^\top Lv \geq 0.
\]

Furthermore, since \( 1_n \) is the unique eigenvector of \( L \) recovering the null eigenvalue, when \( v^\top Lv = 0, v \) must satisfy \( v = 1_n \otimes u \) for some \( u \). Then, Assumption 2 ensures \( v^\top Hv = (1_n \otimes u)^\top H(1_n \otimes u) = u^\top \nabla^2 F(x^*)u > 0 \). This shows that the symmetric matrix \( H + L \) is positive definite.

**Lemma 4** Given Assumptions 1-5, \( \Re \{ \lambda_i \} > 0 \) for all eigenvalues \( \lambda_1, ..., \lambda_{(2n-1)d} \) of \( M = \begin{bmatrix}
D(H + L) & DSR \\
-R^\top S & 0
\end{bmatrix} \).
Proof For any \( i \in [(2n - 1)d] \), \( \lambda_i \) must be a solution to \( \det(M - \lambda I_{(2n-1)d}) = 0 \). First, let us rule out the possibility of having \( \lambda_i = 0 \).

\[
\det(M) = \det\left(\begin{bmatrix} D(H + L) & DSR \\ -R^T S & 0 \end{bmatrix}\right)
= \det\left(\begin{bmatrix} D(H + L) & 0 \\ -R^T S & I_{(n-1)d} \end{bmatrix}\begin{bmatrix} I_{nd} & (D(H + L))^{-1}DSR \\ 0 & R^T S(D(H + L))^{-1}DSR \end{bmatrix}\right)
= \det(D(H + L))\det(R^T S(D(H + L))^{-1}DSR)
= \det(D)\det(H + L)\det(R^T S(H + L)^{-1}SR).
\]

Since \( R^T SSR = (R^T LR) \otimes I_d \geq 0 \), the null space of \( SR \) is 0. Then, \( R^T S(H + L)^{-1}SR \) is positive definite since \( H + L \) is positive definite (Lemma 3). As a result, this confirms that \( \det(M) > 0 \), implying \( \lambda_i \neq 0 \) for all \( i \in [(2n - 1)d] \).

The next step is to look at the characteristic polynomial of \( M \), where we have

\[
0 = \det(M - \lambda I_{(2n-1)d})
= \det\left(\begin{bmatrix} D(H + L) - \lambda I_{nd} & DSR \\ -R^T S & -\lambda I_{(n-1)d} \end{bmatrix}\right)
= \det(-\lambda I_{(n-1)d})\det(D(H + L) - \lambda I_{nd} - DSR(\lambda I_{(n-1)d})^{-1}R^T S)
= \det(D)\det((H + L) - \lambda D^{-1} - \frac{1}{\lambda} SRR^T S)
= \det((H + L) - \lambda D^{-1} - \frac{1}{\lambda} L).
\]

Observe that \((H + L) - \lambda D^{-1} - \frac{1}{\lambda} L\) is a symmetric matrix, and \( \det((H + L) - \lambda D^{-1} - \frac{1}{\lambda} L) = 0 \) implies that there exists a non-zero vector \( v \in \mathbb{R}^{nd} \) for any solution of \( \lambda \) such that

\[
v^T((H + L) - \lambda D^{-1} - \frac{1}{\lambda} L)v = 0.
\]

Since \( L \) is positive semi-definite, \( D^{-1} \) and \((H + L)\) are positive definite, \( v^T L v \geq 0, v^T D^{-1} v > 0, v^T (L + H) v > 0 \). When \( v^T L v = 0 \),

\[
\lambda = \frac{v^T (L + H) v}{v^T D^{-1} v} > 0,
\]

when \( v^T L v > 0 \),

\[
\lambda = \frac{v^T (L + H) v \pm \sqrt{(v^T (L + H) v)^2 - 4 v^T L vv^T D^{-1} v}}{2 v^T D^{-1} v},
\]

certifying that \( \text{Re}[\lambda] > 0 \) in both cases. \(\blacksquare\)
4. Numerical Simulation

In this section, we use a real data-set to show the linear convergence of the training loss in a regression problem. We will investigate the performance of distributed mirror descent with and without integral feedback. We utilize Euler’s discretization scheme on algorithm (8). The resulting discrete-time algorithm for distributed mirror descent with integral feedback is provided below.

\[
\begin{align*}
z_i^{(k+1)} &= z_i^{(k)} - (\nabla f_i(x_i^{(k)}) + y_i^{(k)} + \sum_{j \in \mathcal{N}_i} (x_i^{(k)} - x_j^{(k)})) \Delta t, \\
y_i^{(k+1)} &= y_i^{(k)} + \sum_{j \in \mathcal{N}_i} (x_i^{(k)} - x_j^{(k)}) \Delta t, \\
x_i^{(k+1)} &= \nabla \phi^\ast(z_i^{(k+1)}).
\end{align*}
\] (17)

Details of this discretization is omitted in this manuscript and has been provided in Sun and Shahrampour (2020).

Distance Generating Function for MD: We use the Negative Entropy as our distance generating function \( \phi \), namely,

\[ \phi(x) = \sum_{j=1}^{d} [x]_j \log([x]_j) \implies [z]_i = [\nabla \phi(x)]_i = 1 + \log([x]_i). \]

Based on Section 2.3, the corresponding convex conjugate function \( \phi^\ast \) can be written below,

\[ \phi^\ast(z) = \sum_{j=1}^{d} e^{[z]_j - 1} \implies [x]_i = [\nabla \phi^\ast(z)]_i = e^{[z]_i - 1}. \]

The reason for our choice of DGF is that Kullback–Leibler divergence is one the most commonly used Bregman divergences other than Euclidean distance, which simply reduces the method to distributed gradient descent with integral feedback as in Kia et al. (2015).

Network Structure: We consider a 10-agent cycle network; each agent is connected to its previous and next agent in the loop.

Data Set and Model: We use the Wine Quality Data Set in UCI ML repository Cortez et al. (2009). This is a regression data-set with 11 continuous input variables. Each agent is assigned 400 data instances with no overlap. For agent \( i \in [n] \), we denote the input data and output data as \( A_i \in \mathbb{R}^{400 \times 11} \) and \( b_i \in \mathbb{R}^{400} \), respectively. The model is a linear regression where the loss function is defined as the quadratic error loss, \( f_i(x) = \frac{1}{2} \| A_i x - b_i \|^2 \). We can verify that this setup satisfies Assumptions 1 and 2. The global objective function \( F(x) = \sum_{i \in [n]} \frac{1}{2} \| A_i x - b_i \|^2 = \frac{1}{2} \| A x - b \|^2 \), where \( A, b \) are the stacked version of \( A_i, b_i \), respectively. Moreover, we can calculate the closed form solution of the global problem, \( x^\ast = A^\dagger b \), where \( A^\dagger \) denotes the pseudo-inverse of \( A \).

Note that the selected model is not necessarily optimal for test prediction accuracy, and the aim of this numerical simulation is to show the ability of our proposed algorithm to converge exponentially fast to the optimal loss on a given data set. Finding a better model to fit this data set is not the main focus of this work.
Performance: We provide the trajectory of our proposed algorithm and also a comparison between our work and prior works Li et al. (2016); Shahrampour and Jadbabaie (2018) on distributed mirror descent without integral feedback. In particular, we once run the algorithm without integral feedback using diminishing step-size $\frac{1}{\sqrt{k}}$ to ensure consensus, and once using a constant step-size in optimization, which is unable to reach optimal solution.

The plot of $F(x_1^{(k)}) - F(x^*)$ is shown in Fig. 1, representing the convergence speed of the three algorithms. We can see that our proposed algorithm converges faster than diminishing step-size setup, while the constant step-size setup without integral feedback fails to converge. We plot $\log(F(x_1^{(k)}) - F(x^*))$ in Fig. 1 to further display the exponential convergence (i.e., linear in log-scale) speed of our proposed method.

Figure 1: The trajectory of difference between $F(x)$ and optimal $F(x^*)$ evaluated at agent 1.
Left: linear-scale, Right: log-scale

5. Conclusion

In this paper, we studied the distributed optimization problem, where a network of agents work together to find the optimal solution for a global objective function. We studied a distributed mirror descent algorithm that benefits from the idea of integral feedback. We established that the convergence rate of our algorithm is exponential (locally), which shows the advantage of adopting integral feedback for strongly convex problems. Our claim is supported by empirical results on a real dataset.

Though our work provides exponential convergence rate for strongly convex distributed optimization, more analysis is needed to generalize this work to other network settings, such as dynamic networks and networks with delays. Another interesting direction includes the theoretical analysis of the discretized version of this algorithm, shown in (17). These are open questions left for future works.
