What is already known on this topic?
Congenital hypothyroidism (CH) may be caused by thyroid dysgenesis or thyroid dyshormonogenesis. Thyroid dyshormonogenesis is caused by mutations in genes involved in hormonogenesis and is usually inherited in an autosomal recessive manner. Mutations in the thyroglobulin gene (TG) are a recognized cause of dyshormonogenic CH, which may cause fetal or neonatal goiter.

What this study adds?
The TG c.5686 + 1delG pathogenic variant has not been previously described as causing congenital goitrous hypothyroidism.

Abstract
Congenital hypothyroidism (CH) due to dyshormonogenesis may occur due to mutations in any of the key genes involved in thyroid hormone biosynthesis (TG, TPO, DUOX2, DUOXA2, SLC5A5, IYD, SLC26A4 and SLC26A7). Mutations in the thyroglobulin gene (TG) are frequently associated with goiter, which may present fetally or neonatally, although a spectrum of phenotypes is reported. We present the case of a woman of Eritrean origin who presented in the third trimester of pregnancy in the early stages of labor. Ultrasound at presentation revealed a fetal neck swelling consistent with a goiter. Following delivery by Caesarian section with minimal respiratory support, the infant was found to be hypothyroid with undetectable serum levels of thyroglobulin. Sequencing of the TG revealed a homozygous donor splice site pathogenic variant (c.5686 + 1delG) not previously described in the literature. Levothyroxine treatment resulted in normal growth and psychomotor development. Goitrous CH with inappropriately low thyroglobulin has previously been reported in patients harbouring homozygous single nucleotide substitutions at the same TG donor splice site, which result in exon skipping and retention of malformed thyroglobulin by the endoplasmic reticulum. We conclude that the TG c.5686 + 1delG pathogenic variant is the likely basis for our patient’s fetal goiter and CH, and that the clinical phenotype associated with TG c.5686 + 1delG is comparable to that seen with single nucleotide substitutions at the same site.

Keywords: Congenital goiter, hypothyroidism, thyroglobulin, novel mutation, case report
Introduction

Congenital hypothyroidism (CH) is the commonest neonatal endocrine condition with recent reports demonstrating an incidence of around 1 in 1500 live births (1). Untreated CH can result in profound neurodevelopmental delay but since the introduction of newborn screening for CH in most Western countries, there has been a dramatic improvement in neurodevelopmental outcomes associated with the condition (2). CH is traditionally subdivided into thyroid dysgenesis (TD) and dyshormonogenesis, where TD refers to structural abnormalities of the thyroid including thyroid agenesis or an ectopic/sublingual thyroid gland and dyshormonogenesis describes inadequate thyroid hormone biosynthesis by a normally-located, often goitrous gland, due to molecular defects in the thyroid hormone biosynthetic machinery (3). Dyshormonogenesis usually has an identifiable monogenic basis, involving mutations in thyroglobulin (TG) or genes involved in iodine transport, organification and recycling (SLC5A5, SLC26A4, DUOX2, DUOX2, TPO, SLC26A7, IYD), although oligogenic mutations may also contribute (3). Inheritance of dyshormonogenesis is usually autosomal recessive although CH due to DUOX2, DUOX2 and IYD mutations may also be dominantly inherited.

Dyshormonogenesis may present with goiter in the neonatal period or later, and may rarely be associated with fetal goiter. The mechanical consequences of fetal dyshormonogenic goiter may be associated with significant morbidity. Polyhydramnios may occur due to esophageal compression, and at delivery, neck hyperextension may result in malpresentation. Additionally, neonatal tracheal compression may cause fatal respiratory compromise. Complications can also arise from the underlying foetal thyroid dysfunction that can negatively affect development in utero and subsequent neurodevelopmental outcomes (4,5,6,7).

The management of hypothyroid fetal goiter remains controversial. Since fetal goiter is a marker of serious thyroid dysfunction, many recommend the determination of thyroid function and the consideration of in utero treatment. Although fetal ultrasound, magnetic resonance imaging and amniotic fluid thyroid stimulating hormone (TSH) levels have all been methods suggested for determining fetal thyroid status, these have been shown to have variable levels of accuracy and cordocentesis has been recommended as the gold standard for determining fetal thyroid status. However, it must be taken into account that this may be associated with complications, including cord bleeding, chorioamnionitis and preterm delivery, among others (8).

When considering the decision to treat fetal goiter with associated hypothyroidism, one needs to take into account the size of the goiter, the effect on surrounding structures and associated features such as polyhydramnios. Treatment with both intra-amniotic levothyroxine and administration via the umbilical vein have been described with varying degrees of success, both with regards to reduction in goiter size, reduction in perinatal complications and improvement of fetal thyroid hormone levels (5,6,7). However, conservative management, with radiological surveillance and elective delivery with respiratory support where necessary have also achieved favorable outcomes in some cases (4).

Genetic evaluation has been infrequently undertaken in cases with dyshormonogenic fetal goiter although underlying mutations in TG, TPO, and DUOX2 have been reported in this context (5,6,7).

Case Report

A 35-year-old woman of Eritrean origin was referred to a tertiary obstetric centre due to the finding of a neck mass on fetal ultrasound on presentation at term. Exact gestation was unknown as she had had no previous antenatal follow up or ultrasound scans.

Maternal history was notable for multiparity, with four previous healthy live births with no history of any congenital anomalies or CH. She had no significant past medical history. Her non-consanguineous partner was also Eritrean with no significant past medical history.

On fetal ultrasound exam, a large mass was visualized in the neck and upper chest consisting of two lobes consistent with an enlarged thyroid gland (Figure 1). The mass including both lobes measured 55x63 mm. The trachea was noted to pass through the two lobes with no narrowing noted. Both carotids were displaced laterally by the mass. In addition, the superior vena cava was significantly enlarged, the heart was enlarged and significant tricuspid regurgitation was visualized.

In anticipation of difficulties in airway management following delivery, a Caesarean section was planned with pediatric ear nose and throat and anesthetic staff present. A live female infant was delivered in good condition with Apgar scores of 8 and 9 at one and five minutes respectively. Oxygen saturation was low and the infant was treated with high flow nasal cannula oxygen. Initial examination was notable for a large diffuse neck swelling (Figure 2) and mild respiratory distress with no other abnormal examination findings. The infant was transferred to the neonatal unit for further investigation and management.
In light of prenatal ultrasound findings and clinical examination, initial studies were carried out to investigate thyroid structure and function. Initial thyroid function in the first 24 hours of life, showed primary hypothyroidism although free tri-iodothyronine (fT3) levels were preserved: TSH 272.4 mIU/l (0.4-20), free thyroxine (fT4) 6.3 pmol/L (10-30), and fT3 5.5 pmol/L (2.5-9.8). Thyroglobulin was inappropriately low at 0.7 mcg/L (0-55), without detectable levels of thyroglobulin antibodies (<20 U/mL).

An ultrasound showed enlargement of both lobes of the thyroid gland, including the isthmus. The gland was reportedly of normal texture and was hyperemic. A thyroid technetium scan was also performed (Tc-99m) which demonstrated a diffusely enlarged thyroid gland with diffusely increased uptake.

In view of the laboratory findings of primary hypothyroidism, treatment was commenced on day 1 of life with high dose levothyroxine (18 mcg/kg) with rapid normalization of thyroid function tests. The dose was gradually tapered down accordingly. The child continues endocrine follow up and at the age of 3 years is currently well managed with medical therapy, with a very small goiter which increases in size in accordance with increasing TSH levels. She has no additional medical problems and shows normal growth and psychomotor development.

Due to the association of neonatal goiter with laboratory evidence of hypothyroidism, low serum concentration of thyroglobulin and diffuse uptake of technetium on nuclear scanning, a genetic defect in the thyroglobulin gene was suspected and genetic studies were undertaken with written informed parental consent.

**Genetic Studies**

Sanger sequencing of the thyroglobulin gene (TG, ENST00000220616.9) revealed a novel donor splice site pathogenic variant at the exon 30-intron 30-31 boundary; c.5686 + 1delG which is absent from the gnomAD database (Figure 3) (9). The patient was homozygous for this pathogenic variant. Due to parental reluctance to pursue further genetic testing, DNA was not available from her parents or four siblings for genotyping.

**Discussion**

Thyroglobulin is a large secretory protein which is crucial for thyroid hormone biosynthesis and storage in the thyroid follicular lumen. The TG gene encodes a protein of 2768 amino acids in length including a 19 amino acid N-terminal signal peptide. The recently-solved protein structure of TG has defined five regions (N-terminal domain, core, flap, arm and C-terminal domain) containing domains of type-1 to type-3 cyteine rich TG repeats and a C-terminal choline-esterase-like domain (ChEL) as well as a probable four hormonogenic acceptor tyrosines and five donor tyrosines (10). TG is synthesized in the endoplasmic reticulum (ER) and folds with the assistance of molecular chaperones before trafficking to the apical membrane. The complex protein folding and intracellular trafficking of TG are essential for its normal follicular secretion and require both ER chaperones

Novel Mutation in the Thyroglobulin Gene

and oxidoreductases, as well as specific intramolecular interactions (11). The ChEL domain has an important role in permitting TG intracellular trafficking and secretion and intradomain disulfide bonds between the many cysteine residues in TG are essential for the correct folding of newly synthesized TG (11,12,13).

TG mutations are a common cause of dyshormonogenesis, with an estimated frequency of at least 1:100,000 and are usually inherited in an autosomal recessive manner, although CH has rarely been associated with monoallelic mutations (13,14,15). To the best of our knowledge, TG c.5686+1delG has not previously been reported. However, three different point mutations resulting in single nucleotide substitutions at the same site have been reported in association with congenital goitrous hypothyroidism; TG c.5686+1G>A, 5686+1G>C and 5686+1G>T (16,17,18,19,20,21).

Analysis of patient-derived thyroid tissue has confirmed that TG c.5686+1G>T and c.5686+1G>C mutations cause skipping of exon 30 with a resultant in-frame deletion of 46 amino acids in the TG type III repeat domain, causing the loss of 1 putative N-linked glycosylation site and modifying the TG protein structure (17,20). In common with most pathogenic TG mutations, TG c.5686+1G>T results in TG misfolding and retention within the ER with decreased export to the colloid (16). The fact that TG c.5686+1delG disrupts the same canonical donor splice site guanine residue, suggests that it is highly likely to be pathogenic, although functional studies to confirm this were not undertaken in our study. Due to parental reluctance to pursue further genetic testing, we were unable to obtain DNA to confirm segregation of homozygosity for the mutation with CH phenotype.

Individuals harbouring TG mutations exhibit a spectrum of thyroid dysfunction, ranging from biochemically severe CH to euthyroid goiter (15). Goiter occurs frequently, commonly manifesting in the neonatal period, although onset may be delayed, and a small minority of cases exhibit fetal goiter (6,18). The biochemical hallmark of CH due to a TG mutation comprises an inappropriately low or undetectable goitrogenesis, however its large size and local compressive effects suggest it may have originated some weeks earlier. Lack of ultrasound data from earlier in the pregnancy preclude definitive comments regarding the onset of goitrogenesis, however its large size and local compressive effects suggest it may have originated some weeks earlier. She had significant primary hypothyroidism at birth with low serum total T4 but normal total T3. It was hypothesized that the variable expressivity seen in this family may be partly explained by iodine status, since the elder sibling was raised predominately in an iodine replete region when his sister was aged 2 years may have ameliorated her thyroid dysfunction (17). A homozygous TG c.5686+1G>C mutation was also identified in an iodine replete Pakistani girl, presenting aged 10 years with a massive goiter but normal TSH, subnormal fT4 and raised fT3 levels (20). It is likely that in this case and in the mildly hypothyroid Brazilian sibling, small quantities of mutated thyroglobulin molecules reached the follicular lumen, permitting iodination and synthesis of thyroid hormones, which is facilitated by adequate iodine intake. The elevated fT3/fT4 ratio may be at least in part due to increased thyroidal type 2 deiodinase activity (20).

Urinary iodine was not measured contemporaneously with presentation in this patient but since there is evidence to suggest that iodine intake during pregnancy may be inadequate in some areas of Israel, suboptimal maternal iodine status may have contributed to the fetal goitrogenesis although the patient’s normal fT3 suggests some iodination of mutant TG was occurring in the follicular lumen. Although conservative management of her fetal goiter resulted in a relatively uncomplicated delivery, radiological monitoring for fetal goiter would be advisable during future pregnancies,
given the presumed 25% risk of having another affected child if both parents are heterozygotes for the TG c.5686 + 1 delG pathogenic variant. Additionally, maternal iodine status should be optimized.

**Conclusion**

We report a case of an infant presenting in late pregnancy with a large fetal goiter. CH determined by laboratory studies following delivery and an undetectable serum thyroglobulin. Sequencing of the thyroglobulin gene revealed an as yet unreported homozygous donor splice site pathogenic variant at the exon 30-intron 30-31 boundary; c.5686 + 1delG. Previous single nucleotide substitutions and this site have been described with variable phenotypes including both neonatal goiter, goitrous hypothyroidism, and goitrous euthyroidism. Genetic evaluation, when carried out, revealed skipping of exon 30 in the mRNA and subsequent generation of a shortened protein. Functional evaluation of single nucleotide substitutions at this site demonstrated retention of the TG protein within the ER and resulting decreased export to the follicular lumen. Due to parental refusal further genetic testing on unaffected family members was not carried out. However, based on previous studies as described and the patient’s clinical, biochemical and imaging phenotype, we concluded that this pathogenic variant was the likely cause for the patient’s clinical condition.
