Properties of the partition function of
$\mathcal{N} = 2$ supersymmetric QCD with massive matter

ABSTRACT

We study the different quantum phases that occur in massive $\mathcal{N} = 2$ supersymmetric QCD with gauge groups $SU(2)$ and $SU(3)$ as the coupling $\Lambda/M$ is gradually increased from 0 to infinity. The phases can be identified by computing the exact partition function by saddle-points, combining supersymmetric localization and the Seiberg-Witten formalism. In all cases, we find two phases, a weak coupling and a strong coupling phase, separated by a critical point described by a superconformal field theory or involving superconformal sectors. In crossing the critical point, the dominant saddle-point hops from one singularity of the curve to another one. The theories seem to undergo a second-order phase transition with divergent susceptibility.
Since the works by Seiberg and Witten \cite{1,2}, there have been profound advances in our understanding of the strong coupling dynamics of \( \mathcal{N} = 2 \) supersymmetric gauge theories in four dimensions. \( \mathcal{N} = 2 \) theories exhibit extremely interesting physical phenomena such as asymptotic freedom and electric-magnetic duality, which can be described by means of exact formulas that incorporate all perturbative and non-perturbative contributions in closed form. The presence of quantum phase transitions in theories with massive matter may lead to new insights into the physics of critical phenomena and into the detailed gauge-theory dynamics driving the phase transitions, within a framework with complete analytic control on scaling relations, critical exponents and universality. Exact results for some supersymmetric observables can be obtained by localization techniques. It has been used, in particular, to compute the partition function of general \( \mathcal{N} = 2 \) four-dimensional theories, with any gauge group and matter content \cite{3,4,5}.

Here we consider \( \mathcal{N} = 2 \) supersymmetric QCD with \( SU(N) \) gauge group and \( N_f < 2N \) massive hypermultiplets of equal mass \( M \), an asymptotically free theory. An important problem is to understand if the theory has a smooth behavior when the coupling \( \Lambda / M \) is varied all the way from 0 to infinity, or, on the contrary, it undergoes quantum phase transitions. The presence of possible phase transitions is manifested by non-analytic behavior of physical observables, such as the free energy \( F = - \ln Z \), where \( Z \equiv Z_{\mathcal{N}f}^{SQCD} \) is the
The partition function of the theory on $S^4$ can be computed by using supersymmetric localization \cite{5}, which reduces it to a finite dimensional integral over the Coulomb branch moduli space, $\langle \Phi \rangle = \text{diag}(a_1, \ldots, a_N)$, $\sum_{i=1}^{N} a_i = 0$. More precisely, Pestun’s construction selects an integration contour over the real slice (with our conventions for the $a_i$). The partition function is given by the formula:

$$Z_{SQCD}^{N_f} = \int d^{N-1} a \prod_{i<j} (a_i - a_j)^2 \frac{H^2(a_i - a_j)}{\prod_i H^{N_f}(a_i + M)} e^{(2N-N_f)\ln \Lambda \sum a_i^2} |Z_{\text{inst}}|^2,$$  \hspace{1cm} (1.1)

where

$$H(x) \equiv \prod_{n=1}^{\infty} \left( 1 + \frac{x^2}{n^2} \right) e^{-\frac{x^2}{n}}.$$ \hspace{1cm} (1.2)

Here we have set the radius $R$ of the sphere equal to one. It can be restored by $M \to MR$, $\Lambda \to \Lambda R$ and $a_i \to a_i R$. Computing this integral is obviously difficult, but it can be exactly computed in two limits. One limit is the large $N$ limit discussed in \cite{6,7}. Another limit is the decompactification limit $R \to \infty$ for low rank groups, discussed in \cite{8}.

In the large $N$, Veneziano limit, with fixed $N_f/N$, the instanton factor $|Z_{\text{inst}}|^2$ becomes equal to one and the integral is determined by a saddle-point calculation. If one further takes the decompactification limit $R \to \infty$ the one-loop factor simplifies due to the simple asymptotic form of $\ln H \approx -\frac{1}{2} x^2 \ln x^2$ at $|x| \gg 1$. This leads to surprising physical consequences: the theory undergoes a quantum phase transition of third order at $M = 2\Lambda$. This is dictated by the discontinuity of the third derivative of the free energy with respect to the coupling $\Lambda$ and the non-analytic behavior is due to the appearance of massless components of the hypermultiplet. On the other hand, the 1/2 supersymmetric circular Wilson loop in the fundamental representation can also be computed exactly and it turns out to be discontinuous in the first derivative (discontinuities of the Wilson loop in high antisymmetric representations have also been studied \cite{9}). Similar large $N$ phase transitions appeared in $\mathcal{N} = 2^*$ theory, but in this case with a more complicated phase structure. The large $N$, $\mathcal{N} = 2^*$ theory has been thoroughly investigated in a number of works, with impressive matches with holography \cite{10,11,12,13,14,15}.

For finite $N$, instanton contributions are not suppressed and their contribution is crucial in order to understand the phase structure of the theory \cite{8}. In such a case, the partition function can be more efficiently determined from Seiberg-Witten theory. This yields the prepotential $F$ as a holomorphic function of the moduli $a_i$. The partition function is then given by \cite{3}

$$Z = \int d^{N-1} a \prod_{i<j}^{N} (a_i - a_j)^2 |Z_0|^2,$$  \hspace{1cm} (1.3)

where $Z_0$ is related to the prepotential by the formula

$$2\pi i F(a_i) = \lim_{\epsilon_1, \epsilon_2 \to 0} \epsilon_1 \epsilon_2 \ln Z_0.$$ \hspace{1cm} (1.4)
Here $\epsilon_1, \epsilon_2$ are the equivariant deformation parameters, which, for $S^4$, must be set $\epsilon_1 = \epsilon_2 = 1/R$ \cite{16, 5}. Thus one finds

$$\lim_{R \gg 1} Z^{SQCD}(S^4) = \lim_{R \gg 1} \int d^{N-1} a \ e^{-R^2 S(a_i, M)} ,$$

where

$$S \equiv -\text{Re}(4\pi i F) ,$$

and we have neglected the Vandermonde determinant in the large $R$ limit as it gives a $1/R^2$ contribution to the action. Since $R$ is large, the flat-space partition function $Z = \lim_{R \gg 1} Z^{SQCD}(S^4)$ is determined by saddle-points of $S$. This was the basic idea in \cite{8} and important aspects of this approach were later made more precise in \cite{17}, in the context of $\mathcal{N} = 2^*$ theory with gauge group $SU(N)$. It follows that the exact free energy of the theory is given by

$$F(\Lambda/M) = -\ln Z = -R^2 \text{ Re}(4\pi i F) \bigg|_{a_i = a_i^*}$$

where $a_i^*$ are solutions of

$$\text{Im} \frac{\partial F}{\partial a_i} = \text{Im} (a_D i) = 0 , \quad i = 1, ..., N - 1 ,$$

and $a_D i$ are the usual dual magnetic variables. It should be noted that the resulting free energy depends only on the coupling $\Lambda/M$ and it does not depend on any moduli (since the partition function integrates over the $a_i$). The imaginary part of the period matrix,

$$\tau_{ij} = \frac{\partial^2 F}{\partial a_i \partial a_j} ,$$

is positive definite, as it represents the metric in the moduli space. This proves that the saddle-point calculation is applicable.

The imaginary parts of the $a_D i$ vanish at degenerate points of the Riemann surface, i.e. when some cycles shrink to zero. This implies that the path integral is computed by certain critical points of the prepotential corresponding to $N - 1$ massless BPS dyons, i.e. the path integral is dominated by specific singular curve\cite{4}. Saddle points typically lie inside particular domains of marginal stability \cite{17} (see \cite{18, 19} for related studies in $SU(2)$ SQCD).

Using this approach, in \cite{8} it was shown that the theory with $SU(2)$ gauge group and $N_f = 2$ massive flavors has a phase transition at $\Lambda = 2M$, whose origin is very similar to the large $N$ phase transitions of \cite{6}: at a specific coupling, a component of the electrically charged hypermultiplet becomes massless. The calculation was carried out by determining the relevant saddle-point for the strong coupling phase $\Lambda > 2M$ and noting that there is

\footnote{As it will be clear in the next sections, the converse is not true: not every singularity represents a saddle-point of the partition function integral.}
a singular behavior at $\Lambda = 2M$. The origin of this singular behavior is well understood and it is related to the Argyres-Douglas phenomenon [20]. $\mathcal{N} = 2$ SQCD with massive matter is known to have fixed points at specific values of the parameters, where there is a collision of singularities corresponding to the appearance of mutually non-local massless states [21 22]. These fixed points represent interacting superconformal field theories.

The reason for the appearance of mutually non-local massless states is due to the fact that, when calculating the partition function, we are sitting in a saddle-point, which itself implies the presence of $N - 1$ massless dyons; as we move with the coupling $\Lambda/M$ from 0 to infinity, there is a critical coupling where the degeneracy of the curve increases and also a component of the electrically charged hypermultiplet becomes massless. From this perspective, it is now clear that the critical points of the phase transitions must correspond to fixed points of the type studied in [21 22].

The organization of this paper is as follows. In section 2 we review the hyperelliptic curves describing $\mathcal{N} = 2$ SQCD with massive matter and explain the general procedure used in the following sections. Section 3 is devoted to SQCD with $SU(2)$ gauge group and $N_f = 0, 1, 2, 3$ flavors. After discussing the $N_f = 0$ case in section 3.1, in section 3.2 we first consider the $N_f = 2$ case to complete the picture initiated in [8] by determining the relevant saddle-point also in the weak coupling phase and computing the order of the phase transition. Sections 3.3 and 3.4 deal with the cases of $N_f = 3$ and $N_f = 1$. In general, although the procedure is similar in all cases, there is no universal pattern and the analysis must be made case by case. In section 4, we study SQCD with $SU(3)$ gauge group and $N_f$ fundamental hypermultiplets, by considering three examples, $N_f = 2, 3, 4$ (which illustrate the cases $N_f < N$, $N_f = N$ and $N_f > N$). $SU(3)$ SQCD is described by hyperelliptic curves containing singularities of more general type and many new features appear. Nonetheless, the different phases will be completely characterized in the sense that the partition function will be uniquely determined in terms of the prepotential evaluated at the specific singularities that represent the dominant saddle-point for a given coupling. A discussion on the critical behavior is given in section 4.5. The results are summarized in section 5.

To avoid an excessive overloading of labels and letters, in different cases we make use of the same letters for similar quantities, although in each subsection they are defined independently. For example, in the case of the $SU(3)$ gauge group discussed in section 4, for even $N_f = 0, 2, 4$, the hyperelliptic curve factorizes as $y^2 = Q_+ Q_-$. While we use the same symbols $Q_+$, $Q_-$, they are obviously different for the different cases of $N_f = 0, 2, 4$, discussed in subsections 4.1, 4.3 and 4.2.

2 $\mathcal{N} = 2$ supersymmetric QCD and phase transitions

The curve that describes $\mathcal{N} = 2$ supersymmetric $SU(N)$ gauge theory coupled to $N_f$ fundamental hypermultiplets with arbitrary masses has been found in [23 24] (the curve describing $SU(N)$ pure super Yang Mills was found in [25 26]). For simplicity, here we
consider the case of equal masses. The hyperelliptic curve is given by

\[ y^2 = C(x)^2 - G(x) , \]  
\[ C(x) = x^N + \sum_{k=2}^{N} x^{N-k}s_k + q(x) , \quad G(x) = \Lambda^{2N-N_f}(x + M)^{N_f} , \]  
\[ q(x) = \frac{1}{4} \Lambda^{2N-N_f} \sum_{k=0}^{N_f-N_f} \left( \frac{N_f}{k} \right) x^{N_f-N_f-k} M^k , \]  

where the term \( q(x) \) is absent when \( N_f < N \). The superconformal case corresponds to \( N_f = 2N, M = 0 \). The \( a_n, a_{Dm} \) are the periods of a meromorphic one-form over a basis of homology one-cycles of the curve,

\[ a_n = \oint_{\beta_n} \lambda , \quad a_{Dm} = \oint_{\alpha_m} \lambda , \]

where

\[ \lambda = \frac{x}{4\pi i} d \ln \frac{C - y}{C + y} . \]

In general, the condition (1.8) corresponds to points in moduli space where massless dyons appear. It requires that \( N - 1 \) cycles shrink to zero. In terms of the curve, we must demand that \( N - 1 \) roots of \( y^2 = 0 \) are double roots, so that the curve takes the form

\[ y^2 = (x - x_1)(x - x_2) \prod_{i=1}^{N-1} (x - c_i)^2 . \]

This gives \( N - 1 \) conditions, which fix the \( s_k \) moduli parameters, leaving a discrete set of independent solutions \( \{ s_k \} \). In other words, the saddle-point equations (1.8) correspond to certain zeros of the discriminant that lead to a joining of the branching points in pairs. This is a necessary, but not sufficient, condition, since the cycles that shrink must specifically be those which set \( \text{Im}(a_{Di}) = 0 \) for \( i = 1, ..., N - 1 \). This includes of course the particular solution \( a_{Di} = 0 \). But other singularities correspond to setting some \( a_i = 0 \) and they do not represent saddle-points of the partition function integral.

Following this method, the large \( N \) limit of the theory was studied in [27], generalizing the pure \( (N_f = 0) \) SU(\( N \)) super Yang-Mills theory previously studied in [28] [29]. The resulting conditions implied by (1.8) were solved at large \( N \) in [27] by introducing an eigenvalue density. It was shown that the form (2.6) implies an integral equation for the eigenvalue density, which (at large \( N \)) is identical to the one obtained directly from the localization matrix integral describing the one-loop localization partition function without instantons. In this way one exactly reproduces all the features of the large \( N \) phase transitions found in [6] [7], this time from the study of singularities in the Seiberg-Witten curve.
In this paper we are interested in finite $N$. We will consider examples with $N = 2, 3$ which illustrate the general procedure that can be applied to any gauge group $SU(N)$. Singularities of general type appear when two or more branch points coincide, i.e. when the discriminant of $y^2$, viewed as a polynomial in $x$, vanishes. The discriminant has the general form

$$\Delta(s_k; \Lambda, M) = \Delta_s^{N_f} \Delta_m^m. \quad (2.7)$$

$\Delta_s$ represents the massless $s$-quark singularity and the power of $N_f$ reflects the fact that the quarks transform in the fundamental representation of the global $U(N_f)$ symmetry group of the massive theory. The reason why this is related to a massless $s$-quark singularity is that, for large $M \gg \Lambda$, the singularity occurs at $u \sim M^2$; in such a case the vacuum expectation value of the scalar field is $a \sim \pm M$ and it cancels the bare mass of the hypermultiplet. However, in the strong coupling regime $\Lambda \gg M$ this singularity is associated with the appearance of a magnetically charged massless state.

In general, the discriminant is a polynomial in the multiple variables $s_k$. Consequently, the condition $\Delta = 0$ has multiple solutions. Moreover, there are many distinct solutions which bring the curve to the form (2.6) and solve (1.8). In principle, the dominant saddle-point may be identified by the least-action principle. Computing the action at the singular points is simple in certain limits. Alternatively, the phases can be identified in a solid way by several matching conditions.

In particular, for $M \gg \Lambda$, the hypermultiplets can be integrated out and what remains is supersymmetric Yang-Mills theory without matter. By comparing the respective one-loop $\beta$ functions, one finds that the dynamical scale must be

$$\Lambda_0 = \Lambda^{1 - \frac{N_f}{2N}} M^{\frac{N_f}{N}}. \quad (2.8)$$

Therefore the partition function (hence the saddle-points) of the SQCD theory must coincide with the partition function of pure super Yang-Mills theory (SYM) upon taking this low-energy limit, $\Lambda \to 0$, $M \to \infty$, with $\Lambda_0$ fixed. It will be shown that this implies that the weak coupling phase $\Lambda \ll M$ is determined by a zero of $\Delta_m$. A straight way to see this is that the solutions to $\Delta_s = 0$ move to infinity in the limit $M \to \infty$. On the other hand, we will argue that the strong coupling phase $\Lambda \gg M$ (which is related to the massless limit) is determined, in most of the cases, by a zero of $\Delta_s$ (for $N > 2$, we have $N - 1$ conditions, so we will also need to impose $\Delta_m = 0$). This means that the cycles that shrink at strong and weak coupling must be different: there must be a critical value of $\Lambda$ across which the dominant saddle-point jumps to another singularity.

In addition, we must demand continuity at the critical point: the saddle-points of the subcritical and supercritical phase must coincide on the critical point. It turns out that in many cases this uniquely determines the relevant saddle-points of the two phases.

Additionally, one can explicitly compare the respective actions of the different competing saddle-points. This is a simple calculation in two cases: a) the strong coupling limit $\Lambda \gg M$ and b) the pure SYM limit, $M \to \infty$, $\Lambda \to 0$, with fixed $\Lambda_0$. The reason is that in both cases the theory reduces to an asymptotically free theory without an additional mass
In this case the prepotential satisfies the equation \[30, 31\]
\[
\sum_k a_k \frac{\partial F}{\partial a_k} - 2F = (2N - N_f) \frac{iu}{2\pi} ,
\] (2.9)
with \(u = -s_2 = \frac{1}{2} \langle \text{Tr} \Phi^2 \rangle\). This generalizes the \(SU(2)\), \(N_f = 0\) case first derived in \[32\] and discussions on the massive case can be found in \[33, 34, 35\]. Multiplying by \(i\) and taking the imaginary part, we find that, on the saddle points where \(\text{Im}(a_{Dk}) = 0\), \(\text{Im}(a_k) = 0\), the free energy is given by the remarkable formula
\[
F \bigg|_{a) \text{ or b)} = -R^2 (2N - N_f) \text{Re}(u) .
\] (2.10)
In all examples, the theory will have two phases, \(\Lambda > \Lambda_c\) and \(\Lambda < \Lambda_c\). The formula \((2.10)\) can be applied in the two limits mentioned above, a) and b), to compare the actions of competing saddle-points, when they are present.

Beginning with the solution at \(\Lambda \gg M\), as \(\Lambda/M\) is decreased, a critical point \(\Lambda_c\) will appear when the degeneracy of the curve increases due to a branch point joining one of \(N - 1\) double-degenerate branch points. In all cases, we found that these enhanced singularities involve superconformal theories: they correspond to Argyres-Douglas points, where mutually non-local states become massless. This can be seen from the detailed analysis of degeneracy at the fixed point. The general classification of fixed points for \(SU(N)\) SQCD was given in \[22\], generalizing the \(SU(2)\) case discussed in \[21\].

### 3 Phase transitions in \(SU(2)\) SQCD

For the \(SU(2)\) gauge group it is more convenient to use, instead of (2.1), the Seiberg-Witten curves given in \[2\], where one of the branch points is taken to infinity. The \(SU(2)\) case will be particularly simple because the possible saddle-points are obtained from the zeros of the discriminant in a more straightforward way. For higher-rank groups, the condition \(\Delta = 0\) embodies many types of singularities and most of them are not related to saddle-points of the partition function integral. A case-by-case analysis is required in order to solve all the conditions \(\text{Im}(a_{Di}) = 0\) for \(i = 1, ..., N - 1\).

We will now investigate phase transitions that may occur as the coupling \(\Lambda/M\) is varied from 0 to \(\infty\). These transitions will imply a non-analytic behavior of the free energy. For \(SU(2)\) we have only periods \(a, a_D\). Once the condition \(\text{Im}(a_D) = 0\) is solved for some \(u = u^*(\Lambda/M)\), the period \(a^* = a(u^*)\) is determined and the free energy as a function of \(\Lambda/M\) is given by the formula (1.7). A sign of a phase transition appears when, upon crossing a critical coupling \(\Lambda_c\), the path integral gets dominated by different saddle-point. A more direct sign is when the free energy presents a non-analytic behavior around the critical point. In all cases, the critical point of the phase transition will occur when the s-quark singularity collides with one of the massless monopole or massless dyon singularities.
The BPS mass formula is

\[ M_{\text{BPS}} = \sqrt{2}|Z|, \quad Z = n_m a_D(u) + n_e a(u) + \sum_{i=1}^{N_f} \sigma_i \frac{M_i}{\sqrt{2}}, \quad (3.1) \]

where \( \sigma_i \) are integer and half-integer abelian charges. For massless dyons, this implies a linear relation between \( a_D \) and \( a \), with a possible additive mass term, which does not affect the saddle point equation (1.8) since in our examples the mass is real. Our aim is to completely characterize the different phases in each example by identifying the relevant singularity and to elucidate the main physical features of the phase transition. This procedure implicitly determines the partition function as a function of \( \Lambda/M \), through the above formula (1.7), in a unique way, although deriving an explicit expression in closed form is complicated. The reason is that the prepotential for SQCD with flavors cannot be expressed in closed form in terms of standard special functions in the massive case. Some useful discussions can be found in [36, 37, 38, 39, 19, 40].

3.1 \( SU(2) \) gauge group with \( N_f = 0 \)

It is useful to begin with the \( N_f = 0 \) theory, which describes the low-energy (infinite mass) limit of the \( N_f > 0 \) theories. As explained in [2], in order to study this theory as the low energy limit of SQCD theories with massive hypermultiplets, instead of using the original curve of [1], it is more convenient to describe the dynamics in terms of the curve

\[ y^2 = x^2(x - u) + \frac{1}{4} \Lambda_0^4 \quad x = x(x - x_+)(x - x_), \quad (3.2) \]

where

\[ x_\pm = \frac{1}{2} \left( u \pm \sqrt{u^2 - \Lambda_0^4} \right). \]

With these conventions, particles still have integer charges \( n_m, n_e \) and the structure \( Z = a_D n_m + an_e \) is preserved.

The period \( a \) is defined by integrating the meromorphic form along a loop that goes around 0 and \( x_- \), while \( a_D \) is defined in terms of a loop around 0 and \( x_+ \). Singularities arise at zeros of the discriminant

\[ \Delta \propto \Lambda_0^8 (u^2 - \Lambda_0^4), \quad (3.3) \]

which gives \( u = \pm \Lambda_0^2 \). Near these points, the curve takes the form

\[ y^2 = x \left( x \pm \frac{1}{2} \Lambda_0^2 \right)^2. \]

This gives \( a_D = a \) and \( \text{Im}(a_D) = 0 \). Therefore the singularities at \( u = \pm \Lambda_0^2 \) represent saddle-points in the partition function integral. The dominant saddle-point is \( u = \Lambda_0^2 \) because the free energy (2.10) is smallest in this case:

\[ F = -4R^2 \Lambda_0^2. \quad (3.4) \]
In discussing massive theories with \( N_f > 0 \), the weak coupling phase \( \Lambda \ll M \) must be dominated by this saddle-point, so that the low energy dynamics is the same as in pure SYM. In particular, this ensures a consistent renormalization group flow from the \( N_f > 0 \) theories to the \( N_f = 0 \) theory upon the identification (2.8).

### 3.2 \( SU(2) \) gauge group with \( N_f = 2 \)

This case, with two flavors of equal masses, was discussed in [8], where the saddle-point of the strong coupling phase was identified and it was argued that the theory has a phase transition at \( \Lambda = 2M \). Here we will clarify what happens in the weak coupling phase \( \Lambda < 2M \) and in addition compute the order of the phase transition.

For two massive flavors, the curve is [2]

\[
y^2 = \left( x^2 - \frac{1}{64} \Lambda^4 \right) (x - u) + \frac{1}{4} M^2 \Lambda^2 x - \frac{1}{32} M^2 \Lambda^4 .
\]  

(3.5)

It is convenient to shift \( x \to x + u/3 \) and write

\[
y^2 = (x - e_1)(x - e_2)(x - e_3) ,
\]

with

\[
e_1,3 = \frac{u - \Lambda^2}{16} \pm \frac{1}{2} \sqrt{u + \frac{\Lambda^2}{8}} + \Lambda M \sqrt{u + \frac{\Lambda^2}{8} - \Lambda M} ,
\]

\[
e_2 = -\frac{u}{3} + \frac{\Lambda^2}{8} .
\]

(3.7)

The prepotential \( F(a) \) is obtained from the formula

\[
a_D = \frac{\partial F}{\partial a} ,
\]

(3.8)

where \( a \) and \( a_D \) are period integrals of the meromorphic one-form

\[
\lambda = -\frac{\sqrt{2}}{4\pi} \frac{y \, dx}{x^2 - \frac{\Lambda^2}{64}} .
\]

(3.9)

As usual, this determines \( a \) and \( a_D \) in terms \( u \) and, consequently, \( F(u) \) or \( F(a) \). The period \( a_D \) corresponds to the integral over the cycle encircling \( e_1 \) and \( e_2 \), while \( a \) is an integral over a cycle encircling \( e_2 \) and \( e_3 \). This last cycle also surrounds the pole of the meromorphic one-form \( \lambda \) with residue \( M/\sqrt{2} \). Useful formulas for the periods in terms of elliptic functions can be found in [38–40, 13].

Singularities occur when two branch points collide, i.e. at the zeros of the discriminant

\[
\Delta = \frac{1}{216} \Lambda^4 \Delta^2 \Delta_m \Delta_{m^-} ,
\]

(3.10)
\[ \Delta_s = \Lambda^2 + 8M^2 - 8u, \quad \Delta_{m\pm} = \Lambda^2 + 8u \pm 8\Lambda M. \] (3.11)

One singularity corresponds to \( \Delta_s = 0 \),
\[ u_s = M^2 + \frac{\Lambda^2}{8}. \] (3.12)

The other two singularities, solving \( \Delta_{m\mp} = 0 \), appear at
\[ u_{1,2} = \pm M\Lambda - \frac{\Lambda^2}{8}. \] (3.13)

At \( u = u_s \), the branch point \( e_1 \) coincides with \( e_2 \) provided \( \Lambda > 2M \). In this case one would find \( a_D = 0 \), therefore a solution of the saddle-point equation. However, when \( \Lambda < 2M \), at \( u = u_s \) one has \( e_2 = e_3 \). The singularity at \( u = u_s \) no longer represents a saddle-point, as it does not solve the condition \( \text{Im}(a_D) = 0 \). This can be seen by explicit calculation (see fig. 2a in [8]). The saddle-point must hop to another singularity, implying a phase transition.

At the critical coupling
\[ \Lambda_c = 2M, \] (3.14)
the three branch points \( e_1, e_2, e_3 \) coincide. The curve has a cusp of the form
\[ y^2 = \left( x - \frac{1}{2}M^2 \right)^3. \]

This point describes a superconformal field theory of the Argyres-Douglas type [20], studied in detail in [21]. As shown below, this fixed point represents nothing but the critical point of a second-order phase transition.

**Strong coupling phase \( \Lambda > 2M \)**

The saddle-point equation is
\[ \frac{\partial S(a, M)}{\partial a} = 0 \implies \text{Im} \left( \frac{\partial F}{\partial a} \right) = \text{Im}(a_D) = 0. \] (3.15)

A particular solution is \( a_D = 0 \), which requires that \( e_1 \to e_2 \). As pointed out above, this occurs at
\[ u_s = M^2 + \frac{1}{8}\Lambda^2, \quad \Lambda > 2M, \] (3.16)
where the curve takes the form
\[ y^2 = \left( x - \frac{\Lambda^2}{8} \right)^2 \left( x - M^2 + \frac{\Lambda^2}{8} \right). \] (3.17)

---

2This has also consequences for the stability domains of the BPS spectra in the \( \Lambda < 2M \) and \( \Lambda > 2M \) regimes [19].
In the vicinity of the singularity one has the behavior

\[ a_D \approx c(u - u_s), \quad a \approx a_0 + \frac{i}{\pi} c_0(u - u_s) \ln(u - u_s). \]  

(3.18)

The monodromy around the singularity gives \( a_D \to a_D, \quad a \to a - 2a_D \) and of course it does not affect the existence of a saddle-point. As the fixed point \( \Lambda = 2M \) is reached from above, one finds that \( e_2 \to e_3, y^2 = (x - \frac{1}{2}M^2)^3 \) and the only contribution to \( a \) comes from the mass residue, leading to

\[ a^* = a(u_s) \to \frac{M}{\sqrt{2}} \quad \text{as} \quad \Lambda \to 2M. \]  

(3.19)

At this critical point, one component of the hypermultiplet becomes massless, because the bare mass \( M \) is canceled by the vacuum value, which in the present conventions is \( \sqrt{2}a = M \). The appearance of this massless state at a specific coupling leads to a non-analytic behavior of the free energy. This is exactly the same physical origin as the large \( N \) phase transitions of [6].

As long as \( \Lambda > 2M \), the free energy will be given by \( F(\Lambda/M) = -R^2 \text{Re}(4\pi i F(a^*)) \), where \( a^* \) is the value of \( a \) at \( u = u_s \). The free energy is thus completely determined in the strong coupling phase \( \Lambda > 2M \) in terms of the prepotential as a function of \( \Lambda/M \), computed by sitting on the \( u = u_s \) singularity.

**Weak coupling phase** \( \Lambda < 2M \)

As explained, when \( \Lambda < 2M \), \( u = u_s \) does not correspond to a saddle-point of the integral. In this phase, \( \Lambda < 2M \), the saddle-point equation \( \text{Im}(a_D) = 0 \) is satisfied at the singular point

\[ u \to u_1 = M\Lambda - \frac{\Lambda^2}{8}. \]  

(3.20)

At \( u = u_1 \), \( e_1 \to e_3 \) and the curve becomes

\[ y^2 = \left( x - \frac{1}{2}M\Lambda + \frac{\Lambda^2}{8} \right)^2 \left( x - \frac{\Lambda^2}{8} \right). \]  

(3.21)

\( u = u_1 \) describes the dyon singularity

\[ a - \frac{M}{\sqrt{2}} - a_D = 0. \]  

(3.22)

We have checked that \( \text{Im}(a_D) = 0 \) using the explicit formulas for \( a_D, \ a \) in terms of elliptic functions given in [19].

Substituting \( u \to u_1 \) into the action, one can determine the free energy in the weak coupling phase \( \Lambda < 2M \).

A check that the weak coupling phase has been correctly identified is that the corresponding partition function must match the partition function of pure SYM without matter.
in the $M \to \infty$ limit where the hypermultiplet is decoupled. In the current $N_f = 2$ case, according to (2.8), the limit corresponds to $M \to \infty$, $\Lambda \to 0$, with $M\Lambda \equiv \Lambda_0^2$ fixed. In this limit, the $N_f = 2$ curve reduces to the Seiberg-Witten curve [3, 2] and the singularity at $u = u_1$ approaches the singularity $u = +\Lambda_0^2$ of (3.3). The remaining singularity at $u_2$ is ruled out by the matching conditions: it does not match $u_s$ at the critical point where the two phases meet, nor it matches the dominant saddle-point $u = \Lambda_0^2$ of the pure SYM limit.

**Free energy and critical behavior**

In the subcritical phase $\Lambda < 2M$ the only possible saddle-point occurs at $u = u_1$. However, in the strong coupling phase $\Lambda < 2M$ there are two competing saddle-points, $u_s$ and $u_1$. In this case both values of $u$ solve the condition $\text{Im}(a_D) = 0$. The dominant saddle-point is the one with least action. Taking the limit $\Lambda / M \to \infty$ or, equivalently, the massless limit $M \to 0$, we can make use of the formula (2.10) to obtain

$$F = -2R^2 u.$$  \hfill (3.23)

Thus we have a phase transition where, in crossing $\Lambda_c = 2M$, the saddle-point hops from one singularity to a different one. The order of the phase transition can be computed by looking at the critical behavior of the free energy. We begin with the prepotential, which can be computed as

$$F(u) - F(u_0) = \int_{u_0}^{u} du \ a_D(u)\partial_u a(u) ,$$  \hfill (3.24)

where $u_0$ is any generic point on the real line. We are interested in non-analytic behavior of the free energy at the critical point. The integrals can be carried out explicitly in the neighborhoods of the conformal point. The behavior of $a$ and $a_D$ near the critical point is determined by the scaling dimension of the perturbation associated with $u$, computed in [21]. For $N_f$ flavors, one has

$$[u] = \frac{12}{11 - N_f} .$$  \hfill (3.25)

As usual, we impose that the periods have dimension 1. For the $N_f = 2$ theory, this gives

$$a - \frac{M}{\sqrt{2}} \sim (u - u_c)^{\frac{3}{2}} , \quad a_D \sim (u - u_c)^{\frac{3}{2}} , \quad u_c = \frac{3}{2} M^2 .$$  \hfill (3.26)

This behavior is consistent with the explicit expressions in terms of elliptic functions given in [39, 19]. Then

$$F(u) \sim \text{const.} \ (u - u_c)^{\frac{3}{2}} + \text{analytic} .$$  \hfill (3.27)

Now, particularizing for $u = u_s$ when $\Lambda \geq 2M$, we see that $u_s - u_c \approx \text{const.}(\Lambda - 2M)$, so $F \sim (\Lambda - 2M)^{\frac{3}{2}}$. For $\Lambda < 2M$, one also has $u_1 - u_c \approx \text{const.}(\Lambda - 2M)$ so $F$ has the same
critical exponent as $\Lambda$ approaches $2M$ from below. As a result, the second derivative with respect to $\Lambda$, representing the susceptibility $\chi$, diverges,

$$\chi = -\frac{\partial^2 F}{\partial \Lambda^2} \sim \frac{1}{\sqrt{\Lambda - 2M}},$$

with a critical exponent equal to $-1/2$. Therefore the phase transition is of the second order.

This may be compared with the analogous phase transition occurring in the large $N$ SQCD model, [6, 7], which is third order. In conclusion, the SQCD $SU(2)$ theory with two flavors has a phase transition of a similar origin as the large $N$ phase transition found in SQCD with $N_f < 2N$ flavors discussed in [6, 7]. Just as in the large $N$ phase transitions, the discontinuous behavior is produced by the contribution of massless hypermultiplets to the free energy at the critical point. Unlike the large $N$ phase transitions of [6, 7], where instantons are suppressed and played no role, here the phase transition is induced by instantons [8]. The superconformal fixed point represents the critical point of this transition.

### 3.3 $SU(2)$ gauge group with $N_f = 3$

We consider three flavors of equal masses $M$. The Seiberg-Witten curve is described by

$$y^2 = x^2(x - u) - \frac{1}{64}\Lambda^2(x - u)^2 - \frac{3}{64}M^2\Lambda^2(x - u) + \frac{1}{4}M^3\Lambda x - \frac{3}{64}M^4\Lambda^2.$$  

(3.29)

It has singularities at the zeros of the discriminant

$$\Delta = \Delta_+^3 \Delta_- = c\Lambda^2(u - u_s)^3(u - u_1)(u - u_2),$$

(3.30)

where $c$ is an unimportant numerical constant and

$$u_s = M^2 + \frac{1}{8}\Lambda, \quad u_{1,2} = \frac{1}{512}\left(\Lambda^2 - 96M\Lambda \pm \sqrt{\Lambda(\Lambda + 64M)^2}\right).$$

(3.31)

Let us write the curve in the form

$$y^2 = (x - x_0)(x - x_+)(x - x_-).$$

(3.32)

In the classical region $u \gg M^2, \Lambda^2$, the branch points behave as follows

$$x_0 \approx u, \quad x_{\pm} \approx \pm \frac{i\Lambda}{8} \sqrt{u}.$$ 

(3.33)

We define $a$ in terms of a cycle surrounding $x_-$ and $x_+$, and $a_D$ in terms of a cycle surrounding $x_0$ and $x_-$. 

14
We now consider the behavior of branch points \( x_0, x_+, x_- \) at the three different singularities. Sitting on the s-quark singularity \( u = u_s \) gives \( x_+ = x_- \) for any real (positive) value of \( \Lambda/M \). At this singularity we have

\[
y^2 \bigg|_{u=u_s} = \left( x - \frac{1}{8} M \Lambda \right)^2 \left( x - M^2 + \frac{1}{8} M \Lambda - \frac{\Lambda^2}{64} \right).
\] (3.34)

This, however, gives \( a = M/\sqrt{2} \), leading to a massless electric hypermultiplet, but it does not constitute a solution of the saddle-point equations because \( \text{Im}(a_D) \neq 0 \). Near this point, one has the behavior

\[
a - \frac{M}{\sqrt{2}} \approx c(u - u_s), \quad a_D \approx a_{D0} - \frac{3i}{2\pi} c(u - u_s) \ln(u - u_s),
\] (3.35)

where \( a_{D0} \) depends on \( \Lambda/M \). This leads to the monodromy \( a \to a, a_D \to a_D + 3a - 3M/\sqrt{2} \). Similarly, the singularity at \( u = u_2 \) also sets \( x_+ = x_- \) and is not a solution of the saddle-point equation.

On the other hand, sitting on the monopole singularity \( u = u_1 \), the elliptic curve takes the form \( y^2 = (x - x_+)(x - x_0)^2 \); the branch point \( x_0 \) coincides with \( x_- \) for any real value of \( \Lambda/M > 0 \). As a result, \( a_D = 0 \) (with a monodromy similar as in the \( N_f = 2 \) case). This represents the saddle-point of the partition function integral for any coupling. In particular, note that there is a smooth match with the pure SQCD limit \( M \to \infty \) with \( \Lambda^4 = \Lambda M^3 \) fixed. In this limit, one has \( u_1 \to \Lambda^2_0 \). When \( \Lambda/M \) becomes equal to 8, the curve has a cusp singularity, \( y^2 = (x - M^2)^3 \). This represents a superconformal theory studied in [21].

At the critical point, \( u_s = u_1 \), there are mutually non-local states becoming massless, the squark and the monopole. Indeed, the critical point may be directly obtained by substituting \( u = u_s \) in \( \Delta_+ \Delta_- \) and demanding that \( \Delta_+ \Delta_- = 0 \). This gives

\[
\Delta_+ \Delta_- \bigg|_{u=u_s} = \text{const.} \ (\Lambda - 8M)^3,
\] (3.36)

which vanishes precisely at the critical point, where there is higher degeneracy.

The free energy is computed as in previous cases by evaluating the prepotential at the singularity, this time at \( u = u_1 \), for any \( \Lambda/M \),

\[
F = - \ln Z = -R^2 \text{Re}(4\pi i \mathcal{F}) \bigg|_{u=u_1}.
\] (3.37)

In particular, in the strong coupling limit, we can use (2.10) to obtain the formula

\[
F \bigg|_{\Lambda \gg M} = -R^2 u_1 \bigg|_{\Lambda \gg M} = -\frac{R^2 \Lambda^2}{256}.
\] (3.38)

Note that this value of \( F \) is smaller than the one obtained by sitting on \( u_s \) (which goes to 0 at \( M \to 0 \)). This also reassures that we are in the correct saddle-point. While there is
no jumping of saddle-points dominating the path integral in going across the critical point, the free energy still presents a non-analytic behavior due to the existence of a fixed point with superconformal symmetry. From the scaling dimension of the perturbation associated with $u$, in neighborhoods of the fixed point one obtains the behavior

$$a \sim (u - u_c)^{\frac{3}{2}}, \quad a_D \sim (u - u_c)^{\frac{3}{2}}, \quad u_c = 2M^2. \quad (3.39)$$

This gives

$$\mathcal{F} \sim \text{const.} (u - u_c)^{\frac{3}{2}}. \quad (3.40)$$

The dependence on $\Lambda$ is obtained by sitting on $u = u_1$ and using $u_1 - u_c \sim \frac{M}{8}(\Lambda - 8M)$. Like in the two-flavor case, the susceptibility, $\chi = -\partial^2_\Lambda \mathcal{F}$, is divergent, indicating a second-order phase transition.

### 3.4 $SU(2)$ gauge group with $N_f = 1$

The Seiberg-Witten curve is

$$y^2 = x^2(x - u) + \frac{1}{4}MA^3 x - \frac{1}{64}A^6 = (x - x_0)(x - x_+)(x - x_-). \quad (3.41)$$

The discriminant is now

$$\Delta = -\frac{\Lambda^6}{16} \left( u^3 - 3M^2 u^2 - \frac{9}{8}MA^3 u + \Lambda^3 M^3 + \frac{27\Lambda^6}{256} \right). \quad (3.42)$$

Thus singularities arise at three roots $u_s$, $u_1$, $u_2$ of the cubic polynomial equation $\Delta = 0$. They are distinguished by the behavior at $M \to \infty$, where

$$u_s \approx M^2, \quad u_{1,2} \approx \pm \Lambda_0^2, \quad \Lambda_0^4 \equiv MA^3. \quad (3.43)$$

The critical point occurs when two of these roots meet. That is, when the discriminant of $\Delta$ vanishes. This gives

$$\Lambda = e^{2\pi i \ell \frac{4M}{3}}, \quad \ell = 0, 1, 2. \quad (3.44)$$

At any of these points, there are mutually non-local states becoming massless (quarks, monopoles or dyons). The corresponding interacting superconformal field theory is discussed in [21]. As we are examining the behavior of the theory for real $\Lambda$ between 0 and infinity, the only relevant fixed point will be $\Lambda_c = \frac{4M}{3}$. At the fixed point, one has $u_1 = u_s$ and $y^2 = (x - 4M^2/9)^3$.

In the classical limit $u \gg M^2, \Lambda^2$, the branch points behave as follows

$$x_0 \approx u + O(u^{-1}), \quad x_\pm \approx \pm \frac{i}{8} \Lambda^3 \frac{1}{\sqrt{u}} + O(u^{-1}). \quad (3.45)$$

$a$ is defined as the period integral over the cycle looping around $x_-$ and $x_+$, while $a_D$ as the period integral over the cycle looping around $x_-$ and $x_0$. 

16
One finds the following behavior at the singularities:

\[ u = u_s : \quad x_0 = x_-, \quad \text{for } \Lambda > \frac{4M}{3}; \quad x_+ = x_-, \quad \text{for } \Lambda < \frac{4M}{3}; \]

\[ u = u_1 : \quad x_0 = x_+, \quad \text{for } \Lambda > \frac{4M}{3}; \quad x_0 = x_+, \quad \text{for } \Lambda < \frac{4M}{3}; \]

\[ u = u_2 : \quad x_+ = x_-, \quad \text{for } \Lambda > \frac{4M}{3}; \quad x_+ = x_-, \quad \text{for } \Lambda < \frac{4M}{3}. \]

In the weak coupling phase \( \Lambda < 4M/3 \), \( u_s, u_1, u_2 \) are real and all three roots \( x_0, x_+, x_- \) are real. As a result, the dyon singularity at \( u = u_1 \), where \( x_0 = x_+ \), gives \( \text{Im}(a_D) = 0 \) with \( a_D = a \) (modulo real mass terms). Therefore \( u = u_1 \) represents the saddle-point of the weak coupling phase. As a consistency check, we find that \( u = u_1 \) matches the saddle-point of the pure (\( N_f = 0 \)) SQCD theory in the limit \( M \to \infty \) with \( \Lambda^4 \equiv M\Lambda_0^3 \) fixed, i.e. \( u_1 \to \Lambda_0^2 \). This is not the case for the singularity at \( u = u_s \), which moves to infinity in this limit.

Consider now the strong coupling phase \( \Lambda > 4M/3 \). In this phase, \( u_2 \) remains real while \( u_s \) and \( u_1 \) become complex conjugate, \( u_s = u_1^* \) (at the critical point, one has \( u_s = u_1 \)). \( u = u_s \) provides a solution of the saddle-point equation, with \( a_D = 0 \), corresponding to a monopole singularity. The saddle-point at \( u = u_s \) is unaffected under monodromy, because near a monopole singularity \( a_D \) is invariant. At \( u = u_1 \), one has \( a_D = a \), corresponding to a dyon singularity. The fact that \( u_1 \) and \( u_s \) are complex conjugate suggests that both singular points equally contribute to the partition function integral. We can check the consistency of this picture by repeating the analysis, but now using the curve (2.1). For the present case, it is given by

\[ y^2 = (x^2 - u)^2 - \Lambda^3(x + M). \]  

(3.46)

The discriminant is still given by (3.42) (modulo an overall numerical constant). Sitting on \( u = u_s \), at the critical point \( \Lambda_c = \frac{4M}{3} \), the curve has the cusp singularity

\[ y^2 = \left(x + \frac{2M}{3}\right)^3(x - 2M). \]  

(3.47)

At large \( u \), the four branch points have the behavior

\[ x_{1,2} \approx -\sqrt{u \mp \frac{i\Lambda^3}{2u^2}}, \quad x_{3,4} \approx \sqrt{u \pm \frac{\Lambda^3}{2u^2}}. \]  

(3.48)

We define the periods \( a, a_D \) in terms of one-cycles surrounding \( \{x_1, x_2\} \) and \( \{x_2, x_3\} \), respectively. Then we find that, at \( u = u_1, x_2 = x_3 \) for all \( \Lambda/M \). Hence \( a_D = 0 \) on the \( u = u_1 \) singularity. On the other hand, at \( u = u_s \), we have \( x_2 = x_3 \) for \( \Lambda > \Lambda_c \) but \( x_1 = x_2 \) for \( \Lambda < \Lambda_c \). Thus, \( u = u_s \) solves the saddle-point equation \( \text{Im}(a_D) = 0 \) only in the strong
coupling phase. In this phase the branch points with \( u = u_s \) are related to the branch points with \( u = u_1 \) by complex conjugation.

In the strong coupling limit, \( \Lambda \gg M \), one has

\[
\begin{align*}
   u_s \bigg|_{\Lambda \gg M} &\approx \frac{3}{2\sqrt{3}} \left(1 - i\sqrt{3}\right) \Lambda^2, \\
   u_1 \bigg|_{\Lambda \gg M} &\approx \frac{3}{2\sqrt{3}} \left(1 + i\sqrt{3}\right) \Lambda^2.
\end{align*}
\]

(3.49)

Using (2.10), we find that, either at \( u = u_1 \) or \( u = u_s \), the free energy approaches the value

\[
F \bigg|_{\Lambda \gg M} = -\frac{9}{2\sqrt{3}} R^2 \Lambda^2.
\]

(3.50)

In conclusion, the weak coupling phase \( \Lambda < 4M/3 \) is characterized by sitting on \( u = u_1 \) whereas in the strong coupling phase \( \Lambda > 4M/3 \) there are two saddle-points at \( u = u_s \) and \( u = u_1 \), with \( u_s = u_1^* \) and identical contribution to the partition function integral.

Let us now consider the critical behavior. For the theory with \( N_f = 1 \) flavors, from (3.25) one has

\[
\begin{align*}
   a &\sim (u - u_c)^{\frac{5}{3}}, \\
   a_D &\sim (u - u_c)^{\frac{5}{3}}, \\
   u_c &\sim \frac{4M^2}{3}.
\end{align*}
\]

(3.51)

Near the superconformal point, the prepotential is therefore of the form

\[
\mathcal{F} \sim \text{const.} (u - u_c)^{\frac{5}{3}}.
\]

(3.52)

This gives again a divergent susceptibility \( \chi = -\partial^2 F \), indicating that the theory undergoes a second-order phase transition.

## 4 SQCD with gauge group \( SU(3) \)

For higher rank groups, the structure of singularities in the Coulomb branch is more complicated. The theory has different types of singularities (not only double degeneracy or cusps). Accordingly, the phase dynamics becomes more intricate; now we need to solve all the conditions \( \text{Im} \left(a_{Di}\right) = 0 \) and follow the motion of all branch points along the renormalization group flow. Here we will fully characterize the phases and implicitly determine the partition functions of the various theories by identifying the dominant saddle-points and the specific singularities that govern the critical points of the phase transitions. These singularities represent superconformal points that have been classified in [22]. Some aspects of the structure of the theories at these singular points have been more recently elucidated in [41, 42, 43].

### 4.1 \( SU(3) \) gauge group with \( N_f = 0 \)

It is useful to review some features of the pure super Yang-Mills theory with gauge group \( SU(3) \) without matter multiplets, as this theory describes the low-energy limit of the
Theories with massive flavors considered in the subsections that follows. In this case the curve can be written as \[ y^2 = Q_+(x)Q_-(x) , \quad Q_\pm(x) \equiv (x^3 - ux - v) \pm \Lambda_0^3 . \] (4.1)

The fixed points of this theory have been studied in [20]. Because \( Q_+ - Q_- = 2\Lambda_0^3 \), \( Q_+ \) and \( Q_- \) cannot have the same zeros, as we assume \( \Lambda_0 \neq 0 \). Therefore, the only possibility for four branch points joining pairwise is by demanding that the discriminants \( \Delta_\pm \) of both polynomials \( Q_\pm \) are simultaneously equal to zero. One has

\[ \Delta_\pm = 4u^3 - 27(v \mp \Lambda_0^3)^2 = 0 \quad \rightarrow \quad 0 = \Delta_+ - \Delta_- = 108v\Lambda_0^3 . \] (4.2)

This requires \( v = 0 \) and

\[ u^3 = \frac{27\Lambda_0^6}{4} . \] (4.3)

In particular, for the root \( u = 3\Lambda_0^2/2^\frac{2}{3} \), the curve has the form

\[ y^2 = \left(x - 2^\frac{2}{3}\Lambda_0\right)\left(x + 2^\frac{2}{3}\Lambda_0\right)\left(x - 2^{-\frac{1}{4}}\Lambda_0\right)^2 \left(x + 2^{-\frac{1}{4}}\Lambda_0\right)^2 \] (4.4)

On this singularity, there are two dyonic states becoming massless, and \( \text{Im}(a_{D1}) = \text{Im}(a_{D2}) = 0 \). This is the dominant saddle-point as it has the least action. The free energy \( F = -\ln Z \) for this theory is therefore given by

\[ F = -\frac{18}{2^\frac{2}{3}}R^2\Lambda_0^2 . \] (4.5)

The saddle-point at \( u = 3\Lambda_0^2/2^\frac{2}{3}, v = 0 \), will describe the low-energy limit of the \( SU(3) \) theories with \( N_f < 2N \) massive hypermultiplets considered below.

### 4.2 \( SU(3) \) gauge group with \( N_f = 4 \)

A detailed discussion of singularities and superconformal points in this case was given in [22]. The hyperelliptic curve is

\[ y^2 = Q_+Q_- , \quad Q_\pm = x^3 - ux - v + \frac{1}{4}\Lambda^2(x + 4M) \pm \Lambda(x + M)^2 . \] (4.6)

The branch points are the zeros of \( Q_\pm \), which we shall denote by \( \{x_k^+, x_k^-\} \), \( k = 1, 2, 3 \). In the classical limit, they behave as \( x_k^+ \sim c_k v^\frac{4}{3} + O(v^0) \). They are labelled such that

\[ x_k^+ - x_k^- = \frac{2\Lambda}{3} + O(v^{-\frac{1}{4}}) . \]

The period integrals \( a_k \) are then defined in terms of the contours encircling \( x_{k+1}^+, x_{k+1}^- \), whereas the \( a_{Dk} \) integrals loop around \( x_1^+ \) and \( x_{k+1}^+ \), with \( k = 1, 2 \).

\footnote{We adopt the same choice of one-cycles as in [23]. A general discussion of the monodromies in the classical limit for any \( N, N_f \) can be found in this paper.}
The discriminant is given by

$$\Delta = c\Delta_s^4\Delta_m + \Delta_m, \quad \Delta_s = M^3 - Mu + v - \frac{3}{4}M\Lambda^2,$$

$$\Delta_m = 4u^3 - 27(v \mp \frac{\Lambda}{3}u^2)^2,$$  \hfill (4.7)

with

$$u_\pm = u \mp 2\Lambda M + \frac{\Lambda^2}{12}, \quad v_\pm = v \mp 2\Lambda M^2 - \Lambda^2M \pm \frac{\Lambda^3}{27}.$$ \hfill (4.8)

There is a critical point at $$\Lambda_c = 3M$$, which we will describe below.

In order to identify the saddle-point which is relevant to the strong coupling phase $$\Lambda > 3M$$ we first solve $$\Delta_s = 0$$. This gives

$$v = v_s = Mu + \frac{3}{4}M\Lambda^2 - M^3.$$ \hfill (4.9)

At $$v = v_s$$, two branch points join giving

$$y^2 \bigg|_{v=v_s} = (x + M)^2(x - x_1)(x - x_2)(x - x_3)(x - x_4),$$ \hfill (4.10)

with

$$x_{1,2} = \frac{1}{2} \left( M - \Lambda \pm \sqrt{4u - 3M^2 - 6M\Lambda} \right),$$

$$x_{3,4} = \frac{1}{2} \left( M + \Lambda \pm \sqrt{4u - 3M^2 + 6M\Lambda} \right).$$ \hfill (4.11)

Note that $$x_{1,2}$$ and $$x_{3,4}$$ are exchanged under $$\Lambda \to -\Lambda$$. In order to solve the two saddle-point conditions,

$$\text{Im}(a_{D1}) = 0, \quad \text{Im}(a_{D2}) = 0,$$ \hfill (4.12)

we need another cycle shrinking to zero. From the form of the roots (4.12), we see that at

$$u_s = \frac{3}{4}M^2 + \frac{3}{2}M\Lambda,$$ \hfill (4.13)

the branch points $$x_1$$ and $$x_2$$ collide, giving the behavior

$$y^2 \bigg|_{u_s,v_s} = (x + M)^2 \left(x - \frac{1}{2}(M - \Lambda)\right)^2(x - x_3)(x - x_4),$$ \hfill (4.14)

with

$$x_{3,4} = \frac{1}{2} \left( M + \Lambda \pm 2\sqrt{3M\Lambda} \right).$$ \hfill (4.15)

There are two other possible singular points:

---

4Here we correct a typo in (36), (37) of [22].
1) \( u_1 = \frac{3}{4} M^2 - \frac{3}{2} M \Lambda \). This solves \( \Delta_s = \Delta_{m-} = 0 \). As it will be clear from the discussion below, this does not match the saddle-point of the weak coupling phase at the critical point.

2) \( u_2 = 3M^2 + \frac{1}{4} \Lambda^2 \). This gives a behavior \( y^2 \approx (x + M)^4 \). In the classification of [22], it is a class 3 theory involving superconformal sectors. But neither does this singularity match the saddle-point of the weak coupling phase at the critical point.

We must now check that the saddle-point equations are satisfied at \((u_s, v_s)\). Which cycles contract at \( u = u_s \) and \( v = v_s \) depend on whether we are in the subcritical or supercritical regime. Explicitly, we find

\[
\Lambda > 3M : \quad x_2^+ = x_3^+ = \frac{1}{2}(M - \Lambda) , \quad x_1^+ = x_2^- = -M ,
\]
\[
\Lambda < 3M : \quad x_1^+ = x_3^+ = \frac{1}{2}(M - \Lambda) , \quad x_2^+ = x_2^- = -M . \tag{4.17}
\]

Hence

\[
\Lambda > 3M : \quad a_{D1} = a_{D2} , \quad a_{D1} = a_1 , \quad a_{D2} = 0 , \quad a_1 = 0 . \tag{4.18}
\]

Consider first \( \Lambda > 3M \). The condition \( a_{D1} = a_1 \) (which holds modulo an additive real mass term), solves \( \text{Im}(a_{D1}) = 0 \) because \( a_1 \) is real. Since \( a_{D2} = a_{D1} \), then \( \text{Im}(a_{D2}) = 0 \) as well, and the saddle-point conditions are satisfied. We have checked this by integrating the one-form \( \lambda \) from \( x_1^+ \) to \( x_2^- \) to compute \( a_{D1} \) and from \( x_1^+ \) to \( x_3^+ \) to compute \( a_{D2} \). On the other hand, when \( \Lambda < 3M \), \( \text{Im}(a_{D1}) \) is non-vanishing. Therefore the singularity at \( u = u_s \) and \( v = v_s \) does not solve the saddle-point equations when \( \Lambda < 3M \). Note that the required matching with pure \( N_f = 0 \) SYM at \( M \to \infty \) already implies that in the weak coupling phase the dominant saddle-point must correspond to a different singularity, since \((u_s, v_s)\) moves to infinity in the \( M \to \infty \) limit. The singularity in the moduli space that dominates the partition function integral must be different. This jumping from one singular point to another one in crossing \( \Lambda = 3M \) in turn implies a phase transition.

Sitting first on \( u = u_s, v = v_s \), as the coupling \( \Lambda/M \) is decreased from strong values, we get to a critical point \( \Lambda = 3M \) where five branch points coincide, so that the behavior is

\[
y^2 \bigg|_{u_s,v_s,\Lambda_c} = (x + M)^5(x - 5M) . \tag{4.19}
\]

The curve undergoes maximal degeneration. This corresponds to a class 4 theory representing a strongly interacting superconformal field theory (it includes operators of scaling dimensions \( \frac{2}{3}, \frac{2}{3}, 2 \), see [22] and section 4.5 for more details). Let us now consider the weak coupling phase \( \Lambda < 3M \). The other possible singularities occur when \( \Delta_{m+} = \Delta_{m-} = 0 \). Considering the equation \( \Delta_{m+} - \Delta_{m-} = 0 \), we find a linear equation for \( v \). It gives the solution

\[
v = \tilde{v} \equiv \frac{4(25 \Lambda^2 M^3 + 12 M u^2 + 5 \Lambda^2 M u)}{36u - \Lambda^2 + 108 M^2} . \tag{4.20}
\]

21
Substituting \( v = \tilde{v} \) into \( \Delta_{m+} = 0 \), we obtain a cubic polynomial equation for \( u \):

\[
 u^3 - \frac{\Lambda^2}{18} u^2 + \left( \frac{\Lambda^4}{64} - \frac{3}{2} \Lambda^2 M^2 \right) u + \frac{M^2 \Lambda^4}{216} - \frac{27}{4} M^4 \Lambda^2 = 0 .
\] (4.21)

By construction, the zeros automatically match the solutions (4.13) occurring in the \( N_f = 0 \) theory when \( M \to \infty \) theory when \( M \to \infty \) at fixed \( \Lambda_0^3 = \Lambda M^2 \) (it is automatic because the curve (4.6) of the \( N_f = 4 \) theory reduces to the \( N_f = 0 \) curve (4.1) in this limit). The question is which of the three roots of the cubic equation is the one that matches \((u_s, v_s)\), given in (4.14), at the critical point \( \Lambda = 3M \). There is one real root \( \tilde{u} \) and two complex conjugate roots in the whole interval \( 0 < \Lambda < 3M \). A numerical inspection shows that it is the real root the one that matches \( u_s, v_s \) at \( \Lambda = 3M \). The complex conjugate roots give rise to complex values for \( u, v \) at \( \Lambda = 3M \). It is also the real root the one that approaches \( (\tilde{u}, \tilde{v}) \) at \( \Lambda = \Lambda_c \) and also the one that is consistent with the renormalization group flow to pure SYM. The contracted cycles are as follows:

\[
 (u, v) = (\tilde{u}, \tilde{v}) : \quad x_2^- = x_3^- , \quad x_1^+ = x_3^+ .
\] (4.22)

\( x_1^+ = x_3^+ \) implies \( a_{D2} = 0 \) and \( x_2^- = x_3^- \), together with \( a_{D2} = 0 \), implies \( a_{D1} = a_1 + 2a_2 \). The roots are all real and \( a_1, a_2 \) are real. Thus the saddle-point equations \( \text{Im} \left( a_{D1} \right) = \text{Im} \left( a_{D2} \right) = 0 \) are satisfied (as it is easy to check by explicit integration using (2.5) ). On the other hand, when \( \Lambda > 3M \), at \( (\tilde{u}, \tilde{v}) \) one still has \( x_2^- = x_3^- \). However, now \( x_2^+ = x_3^- \). This implies \( a_1 = a_2, a_{D1} = a_{D2} \). As a result, \( (\tilde{u}, \tilde{v}) \) does not solve the saddle-point equations in the strong coupling phase: the only consistent solution in the strong coupling phase is \((u_s, v_s)\), as described above. Thus the saddle-point jumps from the singularity at \( (\tilde{u}, \tilde{v}) \) to the singularity at \( (u_s, v_s) \) in crossing the critical point.

In conclusion, we have a complete characterization of the two phases of the theory. The theory has two quantum phases and it undergoes a phase transition at \( \Lambda = 3M \). The free energy in each phase is a function of \( \Lambda/M \) and it is obtained from the prepotential as \( F = -R^2 \text{Re}(4\pi i F) \) computed at \( (u_s, v_s) \) in the strong coupling phase and at \( (\tilde{u}, \tilde{v}) \) in the weak coupling phase. Substituting these values for \( u, v \) into the formula for the periods, one may compute \( a_1, a_2 \) as functions of \( \Lambda/M \) and hence the free energy \( F(\Lambda/M) \). In the massless limit – representing the strong coupling limit \( \Lambda/M \to \infty \) – we may again make use of the formula (2.10). This gives

\[
 F \bigg|_{M \to 0} = -2R^2 \Lambda^2 \text{Re}(u_s) \to 0 .
\] (4.23)

In the weak coupling limit \( \Lambda \ll M \), the free energy flows to (4.3). For the general dependence \( F(\Lambda/M) \), in the present theory with \( SU(3) \) gauge group, formulas are much more complicated than those seen in the rank 1, \( SU(2) \) case (see [36, 38] for discussions). Nonetheless, it is possible to understand some features of the critical behavior, which we shall discuss in section 4.5.
4.3 \textit{SU}(3) gauge group with \( N_f = 2 \)

The hyperelliptic curve describing SQCD with two massive flavors of equal masses is
\[ y^2 = Q_+(x)Q_-(x) \tag{4.24} \]
where now
\[ Q_\pm(x) \equiv (x^3 - ux - v) \pm \Lambda^2 (x + M) \tag{4.25} \]
The zeros of \( Q_\pm \) are the branch points appearing at \( \{ x_k^+, x_k^- \} \), \( k = 1, 2, 3 \). We label them in such a way that in the classical limit, where \( v \) is large, \( x_k^+ - x_k^- = O(v^{-1/3}) \). The period integrals \( a_k \) are then defined in terms of the contours encircling \( x_k^+ \) and \( x_k^+ \), whereas the \( a_{Dk} \) integrals loop around \( x_k^+ \) and \( x_k^+ \), with \( k = 1, 2 \).

Singularities arise at zeros of the discriminant, which now reads
\[ \Delta = \Delta_2 \Delta_{m+} \Delta_{m-} \quad \Delta_s = M^3 - Mu + v \tag{4.26} \]
Here \( \Delta_{m\pm} \) are the discriminants of \( Q_\pm \), representing the monopole singularities,
\[ \Delta_{m\pm} = 4(u \mp \Lambda^2)^3 - 27(v \mp M\Lambda^2)^2 \tag{4.27} \]
The theory has two phases, with a critical point at \( \Lambda_c = \frac{3}{2\sqrt{2}} M \). The strong coupling phase \( \Lambda > \Lambda_c \) is found by first solving \( \Delta_s = 0 \). This gives
\[ v = v_s = Mu - M^3 \tag{4.28} \]
At this \( v \), two branch points coincide and the curve takes the form
\[ y^2 \bigg|_{v=v_s} = (x + M)^2(x - x_1)(x - x_2)(x - x_3)(x - x_4) \tag{4.29} \]
\[ x_{1,2} = \frac{1}{2} \left( M \pm \sqrt{4u - 3M^2 - 4\Lambda^2} \right) \quad x_{3,4} = \frac{1}{2} \left( M \pm \sqrt{4u - 3M^2 + 4\Lambda^2} \right) \tag{4.30} \]
As we have two saddle-point equations, \( \text{Im}(a_{D1}) = 0 \), \( \text{Im}(a_{D2}) = 0 \), in addition, we must demand that \( \Delta_{m+} \Delta_{m-} \) vanishes. This will lead to a second cycle contracting to zero. \( \Delta_{m+} = 0 \) has solutions \( u_1 = 3M^2 + \Lambda^2 \) and
\[ u_s = \frac{3}{4} M^2 + \Lambda^2 \tag{4.31} \]
The solutions of \( \Delta_{m-} = 0 \) are similar with the change \( \Lambda^2 \rightarrow -\Lambda^2 \). As it is clear from the analysis below, by demanding continuity with the weak coupling phase, one can rule out the other possible singularities arising from \( \Delta_{m-} = 0 \).

The singularity at \( u_1 \) gives a behavior \( y^2 \sim (x + M)^3 \). In the classification of [22], this corresponds to a class 4 superconformal field theory. It does not solve the saddle-point equations.
On the other hand, at \( u_s, v_s \), we find the behavior

\[
y^2 \bigg|_{u_s, v_s} = (x + M)^2 \left( x - \frac{M}{2} \right)^2 (x - x_3)(x - x_4) , \quad x_{3,4} = \frac{M}{2} \pm \sqrt{2} \Lambda .
\]

(4.32)

We must now inspect what cycles shrink. The answer depends on whether \( \Lambda > \Lambda_c \) or \( \Lambda < \Lambda_c \), as follows:

\[
\begin{align*}
\Lambda > \frac{3}{2\sqrt{2}} M & : \quad x_2^+ = x_3^- = -M, \quad x_1^+ = x_3^+ = \frac{M}{2}, \\
\Lambda < \frac{3}{2\sqrt{2}} M & : \quad x_2^+ = x_3^- = -M, \quad x_1^+ = x_3^+ = \frac{M}{2} .
\end{align*}
\]

(4.33)

Thus, for \( \Lambda > \Lambda_c \) we have \( a_{D2} = 0 \) and \(-a_2 + a_{D1} = a_{D2} \) (modulo a real mass residue), i.e. \( a_{D1} = a_2 \). This solves the saddle-point equations, as one can also explicitly check by numerical integration of (2.5) that \( \text{Im}(a_{D1}) = 0 \). However, for \( \Lambda < \Lambda_c \), we get \( a_{D2} = 0 \) and \( a_2 = 0 \), which does not solve the remaining saddle-point equation \( \text{Im}(a_{D1}) = 0 \). Therefore the partition function must be controlled by a different singularity, implying a phase transition.

When \( \Lambda \) reaches the critical point at \( \Lambda_c = \frac{3}{2\sqrt{2}} M \), the degeneracy increases and

\[
y^2 \bigg|_{u_1, v_s, \Lambda_c} = (x + M)^3 \left( x - \frac{M}{2} \right)^2 (x - 2M) .
\]

(4.34)

The critical point does not have maximal criticality (which would be \( y^2 \sim (x + M)^4 \) for \( N = 3, \ N_f = 2 \)) but it still describes a (class 4) strongly interacting superconformal field theory [22].

The partition function in the weak coupling phase must match the partition function of pure SYM, upon making the identification \( \Lambda_0^3 = \Lambda^2 M \) and taking the limit \( M \to \infty \), \( \Lambda \to 0 \). Comparing with the results of section 4.1, one sees that the relevant saddle-point is found by choosing a solution of the monopole singularity \( \Delta_{m+} = \Delta_{m-} = 0 \) for \( u, v \). It must be noted that the singularity (4.31) of the strong coupling phase, arising from \( \Delta_s = 0 \), moves to infinity as \( M \to \infty \), which is another reason why it cannot describe the saddle-point in the weak coupling phase.

To solve \( \Delta_{m+} = \Delta_{m-} = 0 \), we first consider the linear equation for \( v \) obtained from \( \Delta_{m+} - \Delta_{m-} = 0 \). This gives the solution:

\[
v = \tilde{v} \equiv \frac{2 \left( \Lambda^4 + 3u^2 \right)}{27M} .
\]

(4.35)

Substituting \( \tilde{v} \) into \( \Delta_{m+} = 0 \) we get a quartic equation for \( u \). There are two real roots and two complex conjugate roots. In order to identify which root represents the saddle-point, we must now use the matching conditions, namely consistency with the renormalization group flow to the \( N_f = 0 \) theory and continuity at the critical point. Under the renormalization
group flow $M \to \infty$, $\Lambda \to 0$ with fixed $\Lambda_0^3 = \Lambda^2 M$, the relevant singularity $(\tilde{u}, \tilde{v})$ must approach the saddle-point found in section 4.1, $(\frac{3}{2\sqrt{2}} \Lambda_0^3, 0)$. One real root moves to infinity in the $M \to \infty$ limit, so it is ruled out. The remaining real root $\tilde{u}$ approaches the $N_f = 0$ saddle point and it is the only one that matches $u_s$ at $\Lambda = \Lambda_c$, where we also have $\tilde{v} = v_s$. On this singularity, we find

\[(u, v) = (\tilde{u}, \tilde{v}) : \quad x_2^- = x_3^- , \quad x_1^+ = x_3^+ , \]  

(4.36)

$x_1^+ = x_3^+$ implies $a_{D2} = 0$ and $x_2^- = x_3^-$, together with $a_{D2} = 0$, implies $a_{D1} = a_1 + a_2$. The periods $a_1, a_2$ are real and one has $\text{Im}(a_{D1}) = \text{Im}(a_{D2}) = 0$, as can be checked by numerically computing the period integrals.

The singularity at $(\tilde{u}, \tilde{v})$ also represents a saddle-point in the strong coupling phase $\Lambda > \Lambda_c$, because it still holds that $x_2^- = x_3^-$, $x_1^+ = x_3^+$. Thus, at $\Lambda > \Lambda_c$, we have two competing saddle-points: $(\tilde{u}, \tilde{v})$ and $(u_s, v_s)$. To see which one is dominant, we look at the limit $\Lambda \gg \Lambda_c$. This is the massless limit, where the free energy is computed by (2.10). In this limit, $u_s \to \Lambda^2$ and $\tilde{u} \to \frac{i\Lambda^2}{\sqrt{3}}$. Since $F \to -4R^2 \text{Re}(u)$, it follows that the action is less at $(u_s, v_s)$, the contribution from $(\tilde{u}, \tilde{v})$ being exponentially suppressed. Therefore $(u_s, v_s)$ is the relevant saddle-point in the strong coupling phase. In the strong coupling limit the free energy is given by the remarkably simple formula:

\[
F \bigg|_{\Lambda \gg M} = -4R^2 \Lambda^2 .
\]  

(4.37)

Summarizing, the theory undergoes a phase transition as $\Lambda/M$ is increased from 0 to infinity, with a critical point at $\Lambda_c = \frac{3}{2\sqrt{2}} M$. The critical point is a non-maximally singular point described by a class 4 strongly interacting superconformal field theory.

4.4 $SU(3)$ gauge group with $N_f = 3$

For three flavor hypermultiplets of mass $M$, the hyperelliptic curve takes the form:

\[
y^2 = \left( x^3 - u x - v + \frac{1}{4} \Lambda^3 \right)^2 - \Lambda^3 (x + M)^3 .
\]  

(4.38)

In this case of odd $N_f$, there is no factorization and branch points are now given by the zeros of a sixth-order polynomial. Nonetheless, it is possible to completely determine the phases and the free energy. The discriminant is now given by

\[
\Delta = c\Delta_s^3 \Delta_m , \quad \Delta_s = M^3 - Mu + v - \frac{1}{4} \Lambda^3 .
\]  

(4.39)

In order to identify the correct cycles for the periods $a_1, a_2$ and $a_{D1}, a_{D2}$, we first consider the classical limit of $v$ large, where the curve takes the form

\[
y^2 \approx (x^3 - v)^2 - \Lambda^3 x^3 , \quad v \gg \Lambda^3 , M^3 .
\]  

(4.40)
The branch points are located at

\[ x_k^\pm = \left( \frac{1}{2} \left( 2v + \Lambda^3 \pm \sqrt{\Lambda^6 + 4\Lambda^3v} \right) \right)^{\frac{1}{3}}, \quad (4.41) \]

where \( k = 1, 2, 3 \) corresponds to the three cubic roots. Similarly as in previous cases, the cycles defining the period integrals \( a_k \) loop around \( x_{k+1}^+, x_{k+1}^- \), whereas \( a_{Dk} \) integrals are defined in terms of cycles around \( x_{1}^+ \) and \( x_{k+1}^+ \), with \( k = 1, 2 \). It will be shown below that this theory has two phases with a critical point at

\[ \Lambda_c = 2^{\frac{2}{3}} M. \quad (4.42) \]

In the strong coupling phase \( \Lambda > \Lambda_c \), as in previous cases the relevant saddle-point is found by first solving \( \Delta_s = 0 \). This gives

\[ v = v_s = \frac{\Lambda^3}{4} + Mu - M^3. \quad (4.43) \]

For \( v = v_s \), one finds the behavior

\[ y^2 \bigg|_{v=v_s} = (x + M)^2 p_4(x), \quad p_4(x) = (M^2 - Mx - u + x^2)^2 - \Lambda^3(M + x). \quad (4.44) \]

To find another double degeneracy, we demand that the discriminant of \( p_4(x) \) vanishes. This gives the cubic polynomial equation

\[ u^3 - \frac{9M^2u^2}{2} + \frac{27}{16} u (3M^4 - \Lambda^3M) - \frac{27}{256} (-\Lambda^6 + 16M^6 - 44\Lambda^3M^3) = 0. \quad (4.45) \]

As in the previous examples, the choice of the relevant root is dictated by the requirement of continuity at the critical point. This will select only one root, that we call \( u_s \), as the relevant saddle-point. In the massless limit, the roots are

\[ M = 0: \quad u_1^{(0)} = -\frac{3}{2\pi^2} \Lambda^2, \quad u_2^{(0)} = \frac{3}{2\pi} e^{\frac{4\pi}{\Lambda}} \Lambda^2, \quad u_3^{(0)} = \frac{3}{2\pi} e^{\frac{4\pi}{\Lambda}} \Lambda^2. \quad (4.46) \]

\( u_s \) is defined as the zero of (4.45) that approaches \( u_3^{(0)} \) as \( M \to 0 \).

On the singularity at \( (u_s, v_s) \), the curve has the form

\[ y^2 \bigg|_{v_s,u_s} = (x + M)^2 (x - x_0)^2 (x - e_1)(x - e_2). \quad (4.47) \]

The cycles that contract to zero size can be found by numerical inspection of the behavior of the six branch points. We find that, on the singularity \( (u_s, v_s) \), there are two massless dyons and the equations \( \text{Im}(a_{D1}) = \text{Im}(a_{D2}) = 0 \) are satisfied, provided \( \Lambda > 2^{\frac{2}{3}} M \).
Thus the singularity at \((u_s, v_s)\) represents a saddle-point in the supercritical regime. In the strong coupling limit, the free energy can be computed from (2.10). We get
\[
F \bigg|_{\Lambda \gg M} = -3R^2 \Lambda^2 \Re(u_s) = -\frac{9R^2\Lambda^2}{2^4}.
\]
(4.48)

At the critical point \(\Lambda_c = \frac{2^\frac{2}{3}}{M}\), the curve becomes more degenerate
\[
y^2 \bigg|_{v_s, u_s, \Lambda_c} = x^2(x + M)^3(x - 3M).
\]
(4.49)

In the classification of [22], this is a class 2 theory, representing an interacting superconformal field theory. It was noted in [22] that these fixed points describe an universal class of SCFT appearing for any \(SU(N)\) with odd \(N_f < 2N\); in particular, the dimensions of the relevant operators are independent of \(N\).

The singularity at \(v = v_s\), arising as a solution of \(\Delta_s = 0\), moves to infinity in the \(M \to \infty\) limit. This already implies that the saddle-point of the subcritical phase \(\Lambda < \frac{2^\frac{2}{3}}{M}\) must be different, since \(v = v_s\) cannot satisfy the matching condition with pure SYM. The relevant saddle-point describing the weak coupling phase \(\Lambda < \frac{2^\frac{2}{3}}{M}\) is obtained by solving \(\Delta_m = 0\) only. To have a double degeneracy, we must also demand that the discriminant of \(\Delta_m\) (viewed as a polynomial in \(v\)) vanishes. This gives the solution
\[
\tilde{u}^3 = \frac{27M^3\Lambda^3}{4}.
\]
(4.50)

This matches the solution (4.3) in the \(M \to \infty\) limit at fixed \(\Lambda_0^2 = M\Lambda\). In fact, we must take the real cubic root. Substituting \(\tilde{u}\) into \(\Delta_m = 0\), we find a quartic equation for \(v\) with a double root at
\[
\tilde{v} = \frac{3M\Lambda^2}{2^\frac{2}{3}}.
\]
(4.51)

Note that \(\tilde{v} \to 0\) in the \(M \to \infty\) at fixed \(\Lambda_0^2 = \Lambda M\), in consistency with the renormalization group flow to pure Super Yang-Mills theory. The singularity at \((\tilde{u}, \tilde{v})\) gives rise to the correct structure for \(y^2\):
\[
y^2 = (x - x_1)^2(x - x_2)^2(x - x_3)(x - x_4),
\]
(4.52)
\[
x_{1,2} = \frac{\Lambda \pm \sqrt{\Lambda (2^{8/3}M - 3\Lambda)}}{2^{5/3}}, \quad x_{3,4} = \frac{\Lambda}{2^{2/3}} \pm 2^{2/3}\sqrt{\Lambda M}.
\]
(4.53)

Note that the branch points are real in this phase, since \(\Lambda < \frac{2^\frac{2}{3}}{M}\).

As \(\Lambda\) is increased from 0, we get to the superconformal point \(\Lambda = \frac{2^\frac{2}{3}}{M}\) where the curve takes the form
\[
y^2 = x^2(x + M)^3(x - 3M),
\]
(4.54)
in agreement with (4.49). Furthermore, one can check that no continuous matching is possible between the other roots \(u_{1,2}\) of (1.45) and any solution that matches pure super Yang-Mills theory at low energies.
In conclusion, $SU(3)$ SQCD with three fundamental hypermultiplets of equal mass undergoes a phase transition at $\Lambda_c = 2^{2/3}M$. The partition function in the strong coupling $\Lambda > \Lambda_c$ phase is dominated by the singularity $(u_s, v_s)$, whereas in the $\Lambda < \Lambda_c$ phase is dominated by the singularity $(\bar{u}, \bar{v})$.

Finally, we note the existence of a special point in the strong coupling phase, which occurs at $\Lambda = 2M$, where the branch points simplify, with double degeneracy at $x = -M$ and $x = M$. The curve would get a cusp singularity if one sits on the singularities $u_1$ or $u_2$, corresponding to the roots $u_{1,2}^{(0)}$ in the massless limit (4.46). Although these singularities are ruled out by the requirement of continuity of the partition function at $\Lambda_c = 2^{2/3}M$, it would be interesting to understand if the presence of this special point is reflected into some non-analytic behavior of the free energy.

4.5 Critical behavior

The critical behavior of the free energy can be understood from the analysis of perturbations about the fixed point. We will follow the analysis of [22], to which we refer for further details. We start with the case $N_f = 3$. The critical point of the phase transition is described by a class 2 superconformal theory, arising for odd $N_f$, where the singularity is of the form $y^2 \approx (x + M)^{N_f}$. In this case the scaling dimensions of the perturbations $t_j$ are independent of $N$, depending only on $N_f$,

$$[t_j] = \frac{N_f}{2} - j, \quad j = 0, 1, \ldots, \frac{1}{2}(N_f - 1).$$

(4.55)

Consider a period $a_k$ or $a_{Dk}$ that vanishes at the critical point. Periods have scaling dimension equal to 1. This imply that they have the behavior

$$a_k, a_{Dk} \approx t_j^{\alpha_j}, \quad \alpha_j = \frac{1}{[t_j]}.$$

(4.56)

The leading critical exponent originates from the perturbation associated with the chiral operator of highest scaling dimension $[t_0] = N_f/2$. For this perturbation, we thus find

$$N_f = 3: \quad a_k \approx t_0^{2}, \quad a_{Dk} \approx t_0^{2}.$$

(4.57)

This is the same behavior as in the $SU(2)$ case with $N_f = 3$, as expected since class 2 theories represent a universality class of SCFT with global $SU(N_f)$ flavor symmetry, which are independent of $N$. The perturbation $t_0$ can be identified with $v_s - v_c$ and it vanishes at the critical point as $t_0 \sim \Lambda - \Lambda_c$. Since the leading non-analytic behavior of the prepotential is $\mathcal{F} \sim t_0^{2}$, the susceptibility $\chi = -\partial^2_{\Lambda} \mathcal{F} \to \infty$ as $\Lambda \to \Lambda_c$. Therefore the theory undergoes a second-order phase transition, like in the $SU(2)$ case.

Let us now consider the cases $N_f = 2, 4$. We found that the critical points correspond to class 4 theories, which arise for even $N_f$. These are defined by having a singularity of the form

$$y^2 \approx (x + M)^{p+N_f}, \quad 0 < p \leq N - N_f/2.$$
In the case $N_f = 4$, we found maximal criticality, i.e. $p = N - N_f/2 = 1$, $y^2 \approx (x+M)^5$. The underlying low-energy theory was conjectured [41] to be described by two superconformal field theories coupled by an infrared free, magnetic $SU(2)$ gauge theory (see also [42]). The $\beta$ function of the $SU(2)$ gauge theory may induce logarithmic terms in the prepotential, in which case computing critical exponents is delicate. We can however make an estimate of the leading critical behavior of the periods. Following [22], we consider the perturbation

$$y^2 \approx ((x+M)^3 - t_0) (x+M)^{N_f/2} .$$

(4.59)

The one-form $\lambda$ (2.5) behaves as

$$\lambda \approx t^\alpha_0 , \quad \alpha \equiv \frac{5 - N_f/2}{6} = \frac{1}{2} .$$

(4.60)

Thus the vanishing periods have the behavior

$$N_f = 4 : \quad a_k, a_Dk \approx t_0^{1/2} , \quad t_0 \sim \Lambda - \Lambda_c .$$

Finally, let us consider $N_f = 2$. In this case we found $y^2 \approx (x+M)^3$, corresponding to lower ($p = 1$) criticality (for two flavors, maximal criticality would be achieved by $p = 2$). The low-energy theory for this non-maximally singular point has not yet been studied. By the same arguments of [41], it is plausible that the low energy theory involves non-conformal sectors with running coupling, which may again lead to logarithmic terms in the prepotential around this point. As in the $N_f = 4$ case, we will here provide an estimate of the critical behavior of the periods. We found $a_{D2} = a_1 = 0$, $a_2 = a_{D1}$ at the critical point. The scaling dimensions of the perturbations around this singularity are given by [22]

$$[t_j] = \frac{2(N - j)}{p + 2} = \frac{2(3 - j)}{3} , \quad j = 0, ..., N - 1 .$$

(4.61)

Thus the highest dimension is $[t_0] = 2$, which implies the leading near-critical behavior

$$N_f = 2 : \quad a_1 \approx t_0^7 , \quad a_{D2} \approx t_0^7 , \quad a_{D1} - a_2 \approx t_0^{1/2} .$$

Thus, around the critical point, the periods scale in the same way as in the theory with four flavors. It would be interesting to clarify the critical behavior of the prepotential.

5 Summary

This concludes our survey over the phase structure of $\mathcal{N} = 2$ supersymmetric QCD in four dimensions with gauge groups $SU(2)$ and $SU(3)$. Our method was based on an exact saddle-point evaluation of the partition function and the observation that the saddle-point corresponds to a singularity where $N - 1$ dyons become massless. This fixes $N - 1$ moduli parameters $s_k$ leaving a discrete set of solutions $\{s_k\}$. The dominant saddle-point in each
phase was identified by matching conditions and by the explicit computation of the action in the two limits, \( \Lambda \gg M \) and \( \Lambda \ll M \). In the case \( \Lambda \ll M \), the theory flows to pure super Yang-Mills theory and one of the matching conditions requires the saddle-point calculation to reproduce the pure SYM partition function in this limit. The second matching condition requires continuity at the critical point, which implies that the moduli of the weak and strong coupling phases must coincide at this point. This, along with the least-action principle in the \( \Lambda \gg M \) limit, uniquely determine the saddle points of the two phases in the examples considered here.

The critical point of the phase transition corresponds to a singular point in the Coulomb branch and is described by interacting superconformal theories, whose origin in terms of the emergence of mutually non-local massless states is well understood \([20, 21, 22, 41]\). The scaling dimensions of chiral operators at the fixed point dictate the behavior of the free energy at criticality and thus the order of the phase transition. We have argued that the phase transition is second order in the \( SU(2) \) case for \( N_f = 1, 2, 3 \) and in the \( SU(3) \) case with \( N_f = 3 \).

One interesting problem is understanding the phase structure in the complex \( \Lambda \) plane and the convergence properties of the expansion in powers of \( \Lambda/M \). Another interesting problem concerns the case of the \( \mathcal{N} = 2^* SU(N) \) theory, whose partition function in the weak coupling phase was calculated exactly in \([17]\). A striking feature of this theory is the resurgence of the Wigner semicircle distribution for the eigenvalue density in a coarse-grained form \([6, 10]\), occurring in the strong coupling limit, where results can be compared with holography. Perhaps this feature can also be elucidated by appropriate matching conditions, despite the more complicated phase structure.
