Amplitudes of solar-like oscillations in red giant stars

Evidence for non-adiabatic effects using CoRoT observations

\textbf{ABSTRACT}

\textbf{Context.} A growing number of solar-like oscillations has been detected in red giant stars thanks to CoRoT and \textit{Kepler} space-crafts. In the same way as for main-sequence stars, mode driving is attributed to turbulent convection in the uppermost convective layers of those stars.

\textbf{Aims.} The seismic data gathered by CoRoT on red giant stars allow us to test mode driving theory in physical conditions different from main-sequence stars.

\textbf{Methods.} Using a set of 3D hydrodynamical models representative of the upper layers of sub- and red giant stars, we computed the acoustic mode energy supply rate ($\mathcal{P}_\text{max}$). Assuming adiabatic pulsations and using global stellar models that assume that the surface stratification comes from the 3D hydrodynamical models, we computed the mode amplitude in terms of surface velocity. This was converted into intensity fluctuations using either a simplified adiabatic scaling relation or a non-adiabatic one.

\textbf{Results.} From $L$ and $M$ (the luminosity and mass), the energy supply rate $\mathcal{P}_\text{max}$ is found to scale as $(L/M)^{2.6}$ for both main-sequence and red giant stars, extending previous results. The theoretical amplitudes in velocity under-estimate the Doppler velocity measurements obtained so far from the ground for red giant stars by about 40\%. In terms of intensity, the theoretical scaling law based on the adiabatic intensity-velocity scaling relation results in an under-estimation by a factor of about 2.5 with respect to the CoRoT seismic measurements. On the other hand, using the non-adiabatic intensity-velocity relation significantly reduces the discrepancy with the CoRoT data. The theoretical amplitudes remain 40\% below, however, the CoRoT measurements.

\textbf{Conclusions.} Our results show that scaling relations of mode amplitudes cannot be simply extended from main-sequence to red giant stars in terms of intensity on the basis of adiabatic relations because non-adiabatic effects for red giant stars are important and cannot be neglected. We discuss possible reasons for the remaining differences.

\textbf{Key words.} convection - turbulence - atmosphere - Stars: oscillations - Stars: red giants

1. Introduction

Before CoRoT (launched in December 2006), solar-like oscillations had been detected for a dozen of bright red giant stars either from the ground or from space with MOST (e.g., [Barban et al. 2007]). Thanks to CoRoT and \textit{Kepler}, it is now possible to detect and measure solar-like oscillations in many more (several thousands) red giant stars (e.g., de Ridder et al. 2009, Huber et al. 2010, Bedding et al. 2010, Kallinger et al. 2010, Stello et al. 2011, Mosser et al. 2012).

With such a large set of stars, it is possible to perform ensemble asteroseismology by deriving scaling relations that relate seismic parameters to a few fundamental stellar parameters (e.g. masses, radii, luminosities etc). These approaches are now commonly applied to global seismic parameters, such as the cutoff-frequency or peak frequency (e.g., Miglio et al. 2009, Stello et al. 2009, Kallinger et al. 2010, Mosser et al. 2010). However, scaling relation is used only infrequently for mode amplitudes. The main reason for this is our poor theoretical understanding of the underlying physical mechanisms for mode driving and damping.

Using a large set of red giant stars observed by CoRoT, [Baudin et al. 2011] have derived scaling relations in terms of mode lifetimes and amplitudes. These authors have found that the scaling relation proposed by [Samadi et al. 2007] for the mode amplitude significantly departs from the measured one. This result was recently confirmed by [Huber et al. 2011], Stello et al. 2011 and Mosser et al. 2012 with \textit{Kepler} observations, and is easily understood by noting that [Samadi et al. 2007] established the scaling for \textit{main-sequence} stars only, and only for \textit{mode surface velocity}. Indeed, those results point out that a dedicated theoretical investigation of mode amplitudes in intensity for red giants is needed to provide an adequate theoretical background.

Towards the end of their lives, low-mass stars greatly expand their envelope to become red giant stars. As a consequence, the low density of the envelope favours a vig-
orons convection such that excitation of solar-like oscillations occurs in a medium with very different physical conditions than encountered in the Sun. This introduces new problems about the physical mechanism related to mode driving. For instance, the higher the turbulent Mach number, the more questionable the assumptions involved in the theory (Goldreich & Keeley 1977, Goldreich et al. 1994, Samadi & Goupil 2001, Chaplin et al. 2005, Belkacem et al. 2010).

In addition, red giant stars are characterised by high luminosities and hence have relatively short convective thermal time-scales at the upper most part of their convective envelope. One can therefore expect a stronger departure from adiabatic oscillations because the perturbation of entropy fluctuations related to the oscillations dimensionally depends on the ratio \( L/M \) (where \( L \) is the luminosity and \( M \) the mass). Thus, extreme physical conditions in the uppermost convective regions of red giants raise new questions about the energetic aspects of damped stochastically excited oscillations (more precisely mode driving and damping). In the present paper, we focus on modelling mode driving. We derive scaling relations for red giant stars in terms of mode amplitude (in velocity and intensity) and compare them with the available CoRoT observations.

This paper is organised as follows: from a grid of 3D hydrodynamical models representative for the upper layers of red giant stars, we derive in Sect. 2 theoretical scaling laws for the mode amplitudes in velocity (Sect. 2.1) and in intensity (Sect. 2.4). These scaling laws are then compared in Sect. 3 with seismic data. Finally, Sect. 4 is dedicated to conclusions.

2. Theoretical scaling relations for mode amplitudes

In this section our objective is to compute theoretical scaling relations of mode amplitudes both in terms of surface velocity and intensity. To this end, the mode amplitude will be computed with the help of hydrodynamical 3D numerical simulations.

2.1. Surface velocity mode amplitude, \( v \)

The mean squared surface velocity for each radial mode is given by (e.g. Samadi 2011 and references therein)

\[
v^2(\nu, r) = \frac{\tau(\nu)}{2} \frac{\mathcal{P}(\nu)}{M(\nu, r)},
\]

where \( \nu \) is the mode frequency, \( \mathcal{P} \) the mode excitation rate, \( \tau \) the mode life-time (which is equal to the inverse of the mode damping rate \( \eta \)), \( M \) the mode mass, and \( r \) the radius in the atmosphere where the mode velocity is evaluated. The mode mass \( M \) is defined for radial modes as

\[
M(\nu, r) = \frac{1}{|\xi_r(\nu, r)|^2} \int_0^M |\xi_r(\nu, m)|^2 \, dm,
\]

where \( \xi_r \) is the radial component of the mode eigen-displacement. The quantities \( v \), \( M \) and \( \xi_r \) are evaluated at two relevant layers:

- the photosphere, \( i.e. \; r = R_\odot \) where \( R_\odot \) is the stellar radius;
- at a layer where spectrographs dedicated to stellar seismology are the most sensitive. According to Samadi et al. (2008), for the Sun and solar-type stars, this layer is close to the depth where the potassium (K) spectral line is formed, that is at the optical depth \( \tau_{500 \text{ nm}} \approx 0.013 \). For stars with different spectral type this layer may vary, but by an as yet unknown manner (see the discussion in Samadi et al. 2008). By default we therefore adopt this reference optical depth to be representative for the Doppler velocity measurements for red giant stars. This assumption is discussed in Sect. 3.3.

In Eq. (1), \( \mathcal{P} \) and \( M \) are computed in the manner of Samadi et al. (2008) using a set of 3D hydrodynamical models of the upper layers of sub- and red giant stars. However, this calculation differs from Samadi et al. (2008) in two aspects. First, instead of adopting a pure Lorentzian function for the eddy-time correlation in the Fourier domain, we introduce, following Belkacem et al. (2010), a cut-off frequency derived from the sweeping assumption. Second, the 3D models at our disposal have a limited vertical extent that results in an under-estimation by up to \( \approx 10\% \) of the maximum of \( \mathcal{P} \). To take into account the driving that occurs at deeper layers we extend the calculation to deeper layers using standard 1D stellar models (see below).

The 3D hydrodynamical models were built with the CO5BOLD code (Freytag et al. 2002, Wedemeyer et al. 2004, Freytag et al. 2012). All 3D models have a solar metal abundance. The chemical mixture is based on Asplund et al. (2005). The characteristics of these 3D models are given in Table 1. All models have a helium abundance of \( Y = 0.249 \) and a metal abundance of \( Z = 0.0135 \). The 3D models S1, S2, S3, and S7 correspond to red giant stars while S4, S5 and S6 to sub-giants stars.

For each 3D model, an associated complete 1D model (interior+surface) is computed in such a way that the outer layers are obtained from the 3D model (see Samadi et al. 2008 for details) while the interior layers are computed using the CESAM2Kc code (Morel & Lebreton 2008). In these 1D models, convection is treated according to the Canuto et al. (1996) local formulation of convection. This formulation requires a prescription for the size \( \Lambda \) of the strongest eddies. We assume that \( \Lambda = \alpha H_p \) where \( H_p \) is the pressure scale height and \( \alpha \) a parameter adjusted such that the interior model matches the associated 3D model as detailed in Samadi et al. (2008). The complete models (interior+surface) are from now on referred to as patched models.

The characteristics of the patched models are given in Table 2. We then computed the global acoustic modes associated with each of the patched models using the adiabatic pulsation code ADIPLS (Christensen-Dalsgaard 2008). Finally, the mode lifetimes \( \tau \) are evaluated using the measurements performed by Baudin et al. (2011) see Sect. 3.1.

Our objective is to establish a scaling for the maximum of \( v \) (Eq. 1, \( v_{\text{max}} \) hereafter) as a function of stellar parameters and assuming that the mode lifetime \( \tau \) is known. As shown by Belkacem et al. (2011), the mode lifetime \( \tau \) is expected to reach a plateau at a characteristic frequency, \( \nu_{\text{max}} \). As we will see in Sect. 2.2, the maximum of \( \mathcal{P}/M \) also peaks at \( \nu_{\text{max}} \). Accordingly, to derive a scaling law for \( v_{\text{max}} \), one needs to determine how the ratio \( \mathcal{P}/M \) scales with stellar parameters (see Sect. 2.2).
Among these parameters, apart from the classical fundamental parameters (luminosity $L$, mass $M$, effective temperature $T_{\text{eff}}$, gravity $g$, etc.), we in addition considered the acoustic cut-off frequency $\nu_c$ and the large frequency separation $\Delta \nu$ (see e.g. Christensen-Dalsgaard 1982), since the $g$ and the large frequency separation $\Delta \nu$ are related to the properties of the surface and the latter is to the mean density of the star. These parameters scale as

$$\nu_c = \nu_{\odot, c} \frac{g}{g_{\odot}} \sqrt{\frac{T_{\text{eff,} \odot}}{T_{\text{eff}}}} \, \Delta \nu = \Delta \nu_{\odot} \sqrt{\frac{M}{M_{\odot}} \left( \frac{R}{R_{\odot}} \right)^3} \, ,$$

where quantities labelled with the symbol $\odot$ refer to solar values, $\nu_{\odot, c} = 5100 \muHz$ (see Jiménez 2006 and references therein), and $\Delta \nu_{\odot} = 134.9 \muHz$ (Toutain & Froehlich 1992). The values of $\nu_c$ and $\Delta \nu$ associated with each model are given in Table 2.

Finally, we stress that the characteristic frequency $\nu_{\text{max}}$, at which $\tau$ reaches a plateau and $P/M$ is maximum, is related to a resonance in the uppermost layers of solar-like stars between the thermal time-scale and the modal period (see Bellacem et al. 2011 and reference therein). This is why it scales as the acoustic cut-off frequency $\nu_c$ in very good approximation:

$$\nu_{\text{max}} = \nu_{\text{max,} \odot} \frac{\nu_c}{\nu_{\odot, c}} \, ,$$

where $\nu_{\text{max,} \odot} = 3101 \muHz$.

### 2.2. Scaling relation for $(P/M)_{\text{max}}$

The maximum of $P$ is plotted in Fig. 1 (top) as a function of the ratio $L/M \propto T_{\text{eff}}^4$. This dependence with $T_{\text{eff}}$ and $g$ was already highlighted and explained by Stein et al. (2004) and Samadi et al. (2007) (see also the review by Samadi 2011), and is nicely confirmed by Fig. 1 (top). Indeed, $P_{\text{max}}$ follows a power law of the form

$$P_{\text{max}} = P_{0 \text{max}} \left( \frac{L}{L_{\odot}} \frac{M}{M_{\odot}} \right)^s \, ,$$

with $s = 2.60 \pm 0.08 \, , \quad (6)$

where $P_{0 \text{max}} = (4.2_{-0.8}^{+1.0}) \times 10^{15} \text{s}$. The maximum of $P$ is found to peak at a frequency close to $\nu_{\text{max}}$. We note also that the value of the exponent and the constant $P_{0 \text{max}}$ in Eq. (6) are compatible with the results of Samadi et al. (2007) established on the basis of a small set of 3D models of the surface layers of main-sequence (MS) stars. We thus confirm the validity of this relation from MS to red giant stars.

We turn now to the mode mass, $M$. Because we aim to compare theoretical mode velocities with measurements made from the ground with spectrographs dedicated to stellar seismology, we evaluate $M$ at the optical depth $\tau_{500} = 0.013$ (see Sect. 2.1 and Samadi et al. 2008). For a given model, the mode mass ($M$) decreases rapidly with $\nu$, but above a characteristic frequency close to $\nu_{\text{max}}$ it decreases more slowly. Although $M$ does not have a minimum, we found that, as $P$, the ratio $(P/M)$ reaches a maximum close to $\nu_{\text{max}}$, which scales as given by Eq. (3) and Eq. (5). Therefore, we evaluate $M$ at $\nu = \nu_{\text{max}}$. From now on we label this quantity as $M_{\text{max}}$.

Among the different stellar parameters mentioned in Sect. 2.1 a clear correlation of $M_{\text{max}}$ is found with $g$, $(L/M)$, $\nu_c$ or $\Delta \nu$. However, the more pronounced correlation is found with $\Delta \nu$. We therefore adopt the scaling with $\Delta \nu$. The variation of $M_{\text{max}}$ with $\Delta \nu$ is shown in Fig. 1 (bottom). $M_{\text{max}}$ can be nicely fitted by a power law of the form

$$M_{\text{max}} = M_{0 \text{max}} \left( \frac{\Delta \nu}{\Delta \nu_{\odot}} \right)^p \, , \quad (7)$$

where $M_{0 \text{max}} = (4.5_{-0.1}^{+1.3}) \times 10^{21} \text{ kg}$, and $\Delta \nu$ is given by the scaling relation of Eq. (5).

By using Eq. (6) and Eq. (7), the maximum of the ratio $P/M$ then varies according to:

$$(P/M)_{\text{max}} = (P_{0 \text{max}}/M_{0 \text{max}}) \left( \frac{L}{L_{\odot}} \frac{M}{M_{\odot}} \right)^s \left( \frac{\Delta \nu}{\Delta \nu_{\odot}} \right)^p \, . \quad (8)$$

### 2.3. Scaling relation for $V_{\text{max}}$

Equation (8) now permits us to proceed by considering the scaling law for mode amplitudes, in terms of surface velocities. The maximum of the mode surface velocity, by using Eq. (8) together with Eq. (1), reads

$$V_{\text{max}} = v_0 \sqrt{\frac{T_{\text{max}}}{\tau_0}} \left( \frac{L}{L_{\odot}} \frac{M}{M_{\odot}} \right)^s \left( \frac{\Delta \nu}{\Delta \nu_{\odot}} \right)^p \, , \quad (9)$$

where $\tau_{\text{max}}$ is the characteristic lifetime at $\nu = \nu_{\text{max}}$, and

$$v_0 = \sqrt{\frac{\tau_0}{2} \left( \frac{P_{0 \text{max}}}{M_{0 \text{max}}} \right)} \, , \quad (10)$$

with $\tau_0$ a reference mode lifetime whose values are arbitrary fixed to the lifetime of the solar radial modes at the peak.
frequency, that is $\tau_0 = 3.88$ days. Accordingly, we have $v_0 = 0.41$ m/s.

It is worthwhile to note that our scaling relation (Eq. 9) differs from the result of Kjeldsen & Bedding (2011). This is explained by the fact that the postulated relation of Kjeldsen & Bedding (2011) for mode amplitudes in velocity (their equation 16) does not take the mode masses into account, while this is definitively necessary as seen in Eq. 1.

2.4. Scaling relation for bolometric amplitude

The instantaneous bolometric mode amplitude is deduced at the photosphere according to (Dziembowski 1977; Pesnell 1990)

$$\frac{\delta L(t)}{L} = 4 \frac{\delta T_{\text{eff}}(t)}{T_{\text{eff}}} + 2 \frac{\delta R_s(t)}{R_s},$$

where $\delta L(t)$ is the mode Lagrangian (bolometric) luminosity perturbation, $\delta T_{\text{eff}}(t)$ the effective temperature fluctuation, and $\delta R_s(t)$ the variation of the stellar radius.

Since the second term of Eq. (11) is found negligible in front of $\delta T_{\text{eff}}(t)$, one obtains the rms bolometric amplitudes according to

$$\left( \frac{\delta L}{L} \right)_{\text{rms}} = 4 \left( \frac{\delta T_{\text{eff}}}{T_{\text{eff}}} \right)_{\text{rms}},$$

where the subscript rms denotes the root mean-square.

We now need a relation between $(\delta L/L)_{\text{rms}}$ (or equivalently $(\delta L/L)_{\text{rms}}$) and the rms mode velocity $v_{\text{rms}}$. For convenience we introduce the dimensionless coefficient $\zeta$ defined according to

$$(\delta L/L)_{\text{rms}} = 4 \left( \frac{\delta T_{\text{eff}}}{T_{\text{eff}}} \right)_{\text{rms}} = \zeta \left( \frac{v_{\text{rms}}}{v_0} \right),$$

where $v_0 = 2.0 \pm 0.10$, $M_{\text{max},*} = (8.0^{+2.8}_{-2.1}) \times 10^{30}$ kg and $\Delta \nu$ is given by the scaling relation of Eq. (4).

Combining Eq. (13) with Eq. (9) gives the scaling for the bolometric amplitude

$$\left( \frac{\delta L}{L} \right)_{\text{max}} = \zeta \left( \frac{\delta L}{L} \right)_{\text{rms}} \left( \frac{v_0}{v_{\text{rms}}} \right) \left( \frac{\Delta \nu}{\nu_0} \right)^{p_*} \times \left( \frac{\tau_{\text{max}}}{\tau_0} \right) \left( \frac{L}{M} \right) \left( \frac{L_{\odot}}{M_{\odot}} \right)^{s} \left( \frac{\Delta \nu}{\nu_{\odot}} \right)^{p_*},$$

where $v_0 = 2.0 \pm 0.10$, $M_{\text{max},*} = (8.0^{+2.8}_{-2.1}) \times 10^{31}$ kg and $\Delta \nu$ is given by the scaling relation of Eq. (4).

2.4.1. Adiabatic case

Within the adiabatic approximation, it is possible to relate the mode surface velocity to intensity perturbations (e.g., Kjeldsen & Bedding 1995); this gives:

$$\zeta_{K95} = \sqrt{\frac{T_{\text{eff}}}{T_{\text{eff}}}},$$

which assumes that the modes are quasi-adiabatic, but not only. It supposes that the modes propagate at the surface where they are measured. This approximation is not valid in the region where the modes are measured since in this region they are evanescent. Furthermore, it assumes an isothermal atmosphere. A more sophisticated
quasi-adiabatic approach has been proposed by Severino et al. (2008). The authors went beyond the approximation of isothermal atmosphere by taking into account the temperature gradient as well as the fact that the intensity is measured at constant instantaneous optical depth. Both effects are taken into account by the method described in Sect. 2.4.2, which in addition considers non-adiabatic modes.

We present in Fig. 2 $\zeta_{95}$ as a function of $(L/M)$. The adiabatic coefficient remains almost constant for the type of stars investigated here (sub- and red giant stars). This is obviously because $\zeta_{95}$ varies as the inverse of the square root of $T_{\text{eff}}$.

2.4.2. Non-adiabatic case

We also computed $\zeta$ using the MAD non-adiabatic pulsation code (Grigahcène et al. 2005). This code includes the time-dependent convection (TDC) treatment described in Grigahcène et al. (2005).

This TDC formulation involves a free parameter $\beta$, which takes complex values and enters the perturbed energy equation. This parameter was introduced to prevent the occurrence of non-physical spatial oscillations in the eigenfunctions (see Grigahcène et al. 2005 for details). To constrain this parameter we used the scaling relation between the frequency of the maximum height in the power spectrum ($\nu_{\max}$) and the cut-off frequency ($\nu_c$). When scaled to the Sun, one can use this scaling to infer $\nu_{\max}$ for the models we used and the parameter $\beta$ is then adjusted so that the plateau (or depression) of the computed damping rates coincides (see Belkacem et al. 2012).

Note also that TDC is a non-local formulation of convection and is based on the Gabriel (1996) formalism as explained in Dupret et al. (2006b) and Dupret et al. (2006a). In this framework, non-local parameters related to the convective flux (a) and the turbulent pressure (b) are chosen in the same way as in Dupret et al. (2006b) see their Eqs. (17) and (18), see also Dupret et al. (2006b) so that it fits the solar 3D numerical simulation. This calibration results in $a = 10.4$ and $b = 2.9$ (assuming a mixing-length parameter $\alpha = 1.62$).

For sub- and red giant stars $(L/M \gtrsim 10 L_\odot/M_\odot)$, the non-adiabatic intensity-velocity relation obtained with the MAD code can quite well be fitted by a power law of the form

$$\zeta_{\text{nad}} = \zeta_0 \left( \frac{L}{L_\odot} \frac{M_\odot}{M} \right)^k,$$

where $k = 0.25 \pm 0.05$ and $\zeta_0 = 0.59 \pm 0.07$. For main-sequence stars $(L/M \lesssim 10 L_\odot/M_\odot)$, $\zeta_{\text{nad}}$ remains almost constant (not shown). For the Sun, we find $\zeta_{\text{nad}} \approx 0.95$, which is close to the value expected by definition for the Sun. Therefore, we are then led to multiply $\zeta_{\text{nad}}$ by only a factor 1.05 so that, for the Sun, theoretical $(\delta L/L)_{\max}$ matches the helioseismic measurements. The result is shown in Fig. 2 for the sub- and red giant stars $(L/M \gtrsim 10 (L_\odot/M_\odot))$. The non-adiabatic coefficient increases rapidly with increasing $(L/M)$ while $\zeta_{95}$ remains almost constant. Hence, the higher $(L/M)$, the larger the difference between the non-adiabatic and the adiabatic coefficient ($\zeta_{K95}$).

![Fig. 2. Coefficient $\zeta$ (see Eq. 17) as a function of $(L/M)$ for sub- and red giants. The filled circles correspond to the values $\zeta_{\text{nad}}$ obtained with the MAD non-adiabatic pulsation code (see details in the text). The empty squares correspond to the adiabatic coefficient (Kjeldsen & Bedding 1995) (see Eq. 15). The red line corresponds to a power law of the form $\zeta_0 (L/M)^k$ with $k=0.25$. Both intensity-velocity relations have been calibrated so that for the Sun $\zeta = 1$ (see text).](image-url)

3. Comparison with the observations

We compare in this section theoretical mode amplitudes with seismic measurements made from the ground in terms of Doppler velocity (Sect. 3.2) and from space by CoRoT in terms of intensity (Sect. 3.3). We recall that computing the theoretical mode amplitudes requires knowledge of $\tau_{\max}$ (see Eqs. 9 and 15), which is obtained from a set of CoRoT targets as explained in Sect. 3.1.

3.1. The CoRoT data set

Baudin et al. (2011) have measured the mode amplitudes for 360 CoRoT red giant targets. Among those targets, many show very narrow peaks, close to the frequency resolution of the spectrum, while the others have resolved peaks. About 65% of those targets have a highest mode whose width is sufficiently broad to be fitted with a Lorentzian profile. For those targets, the height of the highest mode, $H_{\max}$, and its lifetime $\tau_{\max}$ are thus derived from the fit procedure. However, it is not excluded that some modes with a width more narrow than the frequency resolution may have been fitted with a Lorentzian profile because of the low signal-to-noise ratio. To exclude those modes, we only considered modes with a width $\Gamma_{\max} = 1/(\pi \tau_{\max})$ broader than twice the frequency resolution of the spectra (which is 0.081 $\mu$Hz). This subset represents about 170 targets for which we have an estimate of the mode lifetime ($\tau_{\max}$) at the peak frequency. For each target of this subset, the maximum of the mode amplitude in intensity ($A_{\max}$) was obtained according to the relation $A_{\max} = \sqrt{H_{\max}/\tau_{\max}}$. Finally, a bolometric correction was applied in the manner of Michel et al. (2009) to convert the apparent intensity fluctuation $A_{\text{bol}}$ into a bolometric amplitude $(\delta L/L)_{\max}$.
3.2. Maximum velocity amplitude ($V_{\text{max}}$)

The mode amplitude in terms of velocity is given by Eq. (9). Calculating $V_{\text{max}}$ requires to know the mode life time $\tau_{\text{max}}$ at the peak frequency. We used the values of $\tau_{\text{max}}$ available for our set of CoRoT targets (see Sect. 3.1). We also determined the ratio $L/M$ as well as $\Delta \nu$. The luminosity and mass of these targets are unknown. However, Baudin et al. (2011) have proposed to derive an estimate of the ratio $L/M$ using the following scaling:

$$\frac{L}{M} \propto \frac{\tau_{\text{eff}}^{7/2}}{\nu_{\text{max}}},$$

(18)

where $\nu_{\text{max}}$ is the frequency of the maximum mode height $H_{\text{max}}$ and $T_{\text{eff}}$ is determined from photometric broadband measurements as explained in Baudin et al. (2011). Note that the scaling law of Eq. (18) assumes that $\nu_{\text{max}}$ scales as $\nu_c$, which scales as $g/\sqrt{T_{\text{eff}}}$ (see Eq. [3]). Concerning $\Delta \nu$, as first established by Stello et al. (2009), Hekker et al. (2009) and Kallinger et al. (2010), there is a clear scaling relation between this quantity and $\nu_{\text{max}}$. We derived this quantity here according to the relation derived by Mosser et al. (2010) from a large set of CoRoT red giant stars:

$$\Delta \nu = 0.280 \nu_{\text{max}}^{0.747}.$$  

(19)

Theoretical values of $V_{\text{max}}$ were compared with the stars whose $V_{\text{max}}$ has been measured so far in Doppler velocity from the ground. We considered the different measurements published in the literature (Frandsen et al. 2002; Barban et al. 2004; Bouche et al. 2005; Carrier et al. 2005a,b; Mosser et al. 2005; Arentoft et al. 2008; Kjeldsen et al. 2008; Mosser et al. 2008; Teixeira et al. 2009; Ando et al. 2010). The values quoted in the literature are generally given in terms of peak amplitudes. In that case they were converted into root-mean-square (rms) amplitudes. Furthermore, we rescaled all amplitudes into intrinsic (by opposition to observed) amplitudes. Measured values of $V_{\text{max}}$ are shown in Fig. 3 (top panel) as a function of $L/M$. We have an estimate of the ratio $L/M$ for only a few stars while for almost all of them we have a seismic measure of $\nu_{\text{max}}$, which is typically more accurate than the determination of the ratio $L/M$. Therefore, we also show $V_{\text{max}}$ in Fig. 3 (bottom) as a function of $\nu_{\text{max}}$. The theoretical values of $V_{\text{max}}$ obtained for our subset of red giants are found to be close to the measurements obtained for the red giant stars observed in Doppler velocity from the ground. Note that the considerable dispersion seen in the theoretical values of $V_{\text{max}}$ comes from the dispersion in the measured value of $\tau_{\text{max}}$. Furthermore, we point out that the parameters $p$, $s$, $P_0$, and $M_0$, which appear in Eq. [5], are mostly determined with quite a large error. The errors associated with the parameters introduce a bias on the theoretical $V_{\text{max}}$, which is shown in Fig. 3 by a red vertical bar. As seen in Fig. 3, the theoretical $V_{\text{max}}$ are found, on average, to be about 30% lower than the measurements.

Using several 3D simulations of the surface of main-sequence stars, Samadi et al. (2007) have found that $V_{\text{max}}$ scales as $(L/M)^{3/2}$ with $sv = 0.7$. As seen in Fig. 3, this scaling law reproduces the MS stars quite well. When extrapolated to the red giant domain ($L/M \gtrsim 10 L_\odot/M_\odot$), this scaling law results for $V_{\text{max}}$ in values very close to our present theoretical calculations.

The mode masses $M_{\text{max}}$ were so far evaluated a the reference optical depth $\tau_{500 \text{ nm}} = 0.013$ (see Sect. 2.1). We now discuss the sensitivity $M_{\text{max}}$ to the optical depth at which they are computed. To evaluate our sensitivity to this choice, we alternatively computed the theoretical $V_{\text{max}}$ at the photosphere and at an optical depth ten times lower than our reference level, that is at $\tau_{500 \text{ nm}} = 10^{-3}$. Theoretical $V_{\text{max}}$ are found to be $\sim 30\%$ lower at the photosphere and higher by $\sim 20\%$ at the optical depth $\tau_{500 \text{ nm}} = 10^{-3}$. This result illustrates at which level $V_{\text{max}}$ is sensitive to the depth where the acoustic modes are supposed to be measured. This depth is not well known, however, but we believe that it should be located between the photosphere and our reference optical depth.
3.3. Maximum bolometric amplitude \((\delta L/L)_{\text{max}}\)

3.3.1. Adiabatic case

We computed \((\delta L/L)_{\text{max}}\) according to Eq. (15) using the scaling law given by Eq. (9) for \(v\) and assuming the adiabatic coefficient \(\zeta_{\text{K95}}\) (Eq. (16)). Fig. 4 (top) shows \((\delta L/L)_{\text{max}}\) as a function of ratio \((L/M)\), where this ratio is estimated according to Eq. (18). We also plotted the mode amplitudes measured for a small sample of CoRoT main-sequence stars (see [Baudin et al. 2011] and references therein). Theoretical \((\delta L/L)_{\text{max}}\) under-estimates the amplitudes measured on the CoRoT red giant stars by a factor of about 2.5.

3.3.2. Non-adiabatic case

We computed \((\delta L/L)_{\text{max}}\) according to Eq. (15) assuming the non-adiabatic scaling law established in Sect. 2.4.2 (see Eq. (17)) for \(\zeta\). The result is shown in Fig. 4 (bottom). Using the non-adiabatic coefficient results in an increase of the bolometric amplitude by a factor \(\sim 1.5\) compared to the calculations based on the adiabatic coefficient. This renders the theoretical bolometric amplitude closer to the observations.

We have plotted in Fig. 5 the histogram of the relative difference between observed and theoretical \((\delta L/L)_{\text{max}}\), that is, the histogram of the quantity \(\gamma \equiv (A^\text{theo} - A)/A\), where \(A\) is the theoretical amplitude and \(A^\text{obs}\) the observed one. The dispersion seen in the histogram is due both to the errors associated with the data and the fact that we observe a heterogeneous population of stars with different chemical abundance.

The red horizontal bar shows the bias introduced by the 1-\(\sigma\) errors associated with the determination of the parameters \(p_*, s, \varpi_0, M_{\text{O/S}}\), and \(\zeta_0\) as well the measurement of \((\delta L/L)_{\text{rms}}\) and \(v_{\text{rms}}\) (see Eq. (3)). The median of \(\gamma\) is close to 0.8 (the vertical dashed line). This means that theoretical amplitudes remains, on average, \(\sim 40\%\) below the CoRoT measurements.

4. Conclusion

4.1. Theoretical scaling relation for the velocity mode amplitude

We have extended the calculations performed by Samadi et al. (2007) for main-sequence stars to sub- and red giant stars. We found that the maximum of the mode excitation rate, \(T_{\text{max}}\), scales approximately as \((L/M)^s\) with \(s = 2.60 \pm 0.08\). Accordingly, for sub- and red giant stars, theoretical \(T_{\text{max}}\) scales in same way as for the main-sequence stars.

We also found that the mode mass at the peak frequency, \(M_{\text{max}}\), which was evaluated at a reference level in the atmosphere, scales as \(\Delta v \propto (M/R^3)^{1/2}\), with \(p = 2.1 \pm 0.1\). Since \((M/R^3)\) represents also the mean density, we have that \(M_{\text{max}}\) scales almost linearly as the inverse of the star mean density. This tight relation still remains to be understood, however.

From the scaling laws for \(M_{\text{max}}\) and \(T_{\text{max}}\), we finally derived a scaling law for the maximum of the mode velocity,

\[
V_{\text{max}} \propto (\tau_{\text{max}})^{1/2} \left( \frac{L}{M} \right)^{n/2} \left( \frac{M}{R^3} \right)^{p/4},
\]

which has the following form:

\[
V_{\text{max}} \propto \left( \frac{\tau_{\text{max}}}{M} \right)^{1/2} \left( \frac{L}{M} \right)^{n/2} \left( \frac{M}{R^3} \right)^{p/4},
\]

where \(\tau_{\text{max}}\) is the mode lifetime at the peak frequency.

Using CoRoT data, Baudin et al. (2011) have found that \(\tau_{\text{max}}\) scales approximately as \(T_{\text{eff}}^m\) where \(m = 16.2 \pm\)
The mode amplitudes are sensitive to the layer at which they are evaluated, which must in principle correspond to the height in the atmosphere at which spectrographs dedicated to stellar seismology are the most sensitive (See Sect. 2.1, Sect. 3.2, and Samadi et al. [2008]). However, the uncertainty associated with the lack of knowledge of this layer introduces an uncertainty on the empirical relation which should not exceed ~30% (see Sect. 3.2).

The discrepancy with the velocity measurements can also be attributed to the under-estimation of the mode driving. It is not clear which part of the excitation model might be incorrect or incomplete. Nevertheless, we believe that a possible bias can arise from the way oscillations are currently treated in the region where the driving is the most efficient (i.e. the uppermost part of the convective region). Indeed, in this region the oscillation period, the thermal time-scale and the dynamical time-scale are of the same order, making the coupling between pulsation and convection stronger and energy losses more significant (see e.g. Baudin et al. [2011] and references therein). We have compared non-adiabatic and adiabatic eigenfunctions computed for the global standard 1D model. The non-adiabatic eigenfunctions obtained with the MAD code differ from the adiabatic ones only in a small fraction of the excitation region. We found a negligible difference between excitation rates computed with non-adiabatic eigenfunctions and those computed with adiabatic eigenfunctions. However, we point out that the underlying theory is based on a time-dependent version of the mixing-length theory, which is well known to be a crude formulation of convection. Therefore a more realistic and consistent non-adiabatic approach that does not rely on free parameters and that includes constraints from 3D hydrodynamical models is required.
Finally, part of the differences with amplitudes \((\delta L/L)_{\text{max}}\) measured by CoRoT can be attributed to the intensity-velocity relation. Indeed, if we suppose that the mode masses are correct, then we must multiply the mode excitation rates by a factor \(\sim 1.5\) to match the velocity measurements. In that case only a difference of about 20% with the observed \((\delta L/L)_{\text{max}}\) remains, which must then be attributed to the intensity-relation. The intensity-relation strongly depends on the way non-adiabatic effects are treated, and as mentioned above, the current non-adiabatic treatment is based on a crude description of the convection and its inter-action with pulsation.

Acknowledgements. The CoRoT space mission, launched on December 27 2006, has been developed and is operated by CNES, with the contribution of Austria, Belgium, Brasil, ESA, Germany and Spain.
