Abstract

Improved management of soil carbon (C) and nitrogen (N) storage in agro-ecosystems represents an important strategy for ensuring food security and sustainable agricultural development in China. Accurate estimates of the distribution of soil C and N stores and their relationship to crop yield are crucial to developing appropriate cropland management policies. The current study examined the spatial variation of soil organic C (SOC), total soil N (TSN), and associated variables in the surface layer (0–40 cm) of soils from intensive agricultural systems in 19 counties within Henan Province, China, and compared these patterns with crop yield. Mean soil C and N concentrations were 14.9 g kg⁻¹ and 1.37 g kg⁻¹, respectively, whereas soil C and N stores were 4.1 kg m⁻² and 0.4 kg m⁻², respectively. Total crop production of each county was significantly, positively related to SOC, TSN, soil C and N store, and soil C and N stock. Soil C and N were positively correlated with soil bulk density but negatively correlated with soil porosity. These results indicate that variations in soil C could regulate crop yield in intensive agricultural systems, and that spatial patterns of C and N levels in soils may be regulated by both climatic factors and agro-ecosystem management. When developing suitable management programs, the importance of soil C and N stores and their effects on crop yield should be considered.

Introduction

Safeguarding food security and ensuring sustainable development are two fundamental goals of intensive agriculture in China [1,2]. Increasing soil C and N sequestration while reducing C and N emissions from agricultural fields are important aspects of sustainable farming and these goals can be achieved through improvement in soil quality [1,3]. This requires a better understanding of the functional relationship between crop yield and soil organic C and N stores.

Indeed, variations in soil C and N stores may closely regulate crop yield, although published data on the relationship between these parameters are inconsistent. Some studies have reported a positive correlation between soil C and N and crop yield [4,5], whereas other studies have found no significant relationship between these parameters [6,7]. Lal (2006) reported that the relationship between soil organic C and crop yield may vary between patterns that are sigmoidal, linear, or exponential [8]. Clearly, the existence of such variability warrants further investigation.

Soil C and N stores in crop lands, especially in the topsoil layer, are potentially greatly affected by human activity; thus, understanding the spatial pattern of soil C and N stores on a regional scale is crucial to developing a management strategy for improving soil fertility [1,2]. Spatial variation in soil C and N stores in agro-ecosystems has been widely reported [9,10,11], including from the northern [12,13], eastern [14], and southern [15,16] regions of China. Since these reports from China were based on two national surveys from 1960 and 1983, such data may have limited use in helping to develop management strategies based on current practices [17]. Therefore, in order to better understand the spatial patterns and their relationship to crop yield, it is necessary to update regional soil organic C and N information with contemporary measurements, especially for intensively-used crop land.

Henan Province is the second largest area of crop production in China (China National Bureau of Statistics). To produce an adequate supply of food for the domestic population, unsustainable production methods have often been used in this province. Historically, intensive production based on an annual wheat-maize rotation has been used to achieve high crop yield. This practice, however, has resulted in badly degraded agricultural soils, causing erosion and a loss of good soil structure. More than 600 kg N ha⁻¹ annually has been applied in this production area, resulting in an increase in soil acidity [18]. Based on the determination that crop yields in China will need to increase from 50 billion in 2010 to 65 billion kg in 2020, the provincial crop lands in Henan Province...
will continue to play an important role in food production. Such goals create the challenge of improving soil quality, enhancing soil fertility, and mitigating C and N loss, while achieving food security and practicing sustainable agriculture. A better understanding of the spatial variability of soil organic C and N, and their relationship to crop yield, should help to develop management practices that are designed to meet this challenge [1,19].

The objective of the present study was to characterize the spatial distribution of C and N stores in intensively cultivated counties within the Henan Province of China and to determine the relationship between crop yield and soil organic C and N.

Materials and Methods

Statement: We have field permits for sampling soil in each of the field sites within each county of Henan Province, China. All of the sampling sites are privately owned, and there was no potential impact on any endangered or protected species among these sampling sites.

Study site

The study was carried out in 19 counties within Henan Province, located in central China (Figure 1). Map data were obtained from the National Geomatics Center of China (http://ngcc.sbsm.gov.cn/) using ArcGIS software. As of 2009, the human population of Henan was about 9.9 x 10^7 persons. The Province is
approximately 167,000 km$^2$ in land area, lying within the
monsoonal temperate zone. It has a cultivated land area of 79,
260 km$^2$ for the production of wheat and maize. There are three
dominant soil types in Henan Province: Yellow-cinnamon soil
(Eutric Cambisols in FAO taxonomy), Sajiang black soil (Eutric
Vertisols/Gleyic Cambisol), and Fluvo-aquic soil (Fluvisol in FAO
taxonomy) [20]. Mean annual precipitation ranges from 400 to
1000 mm among the counties of the study, with ~70% of it
occurring from July to September; mean annual temperature
ranges from 13.6 to 15 °C (Figure 2). Cultivated agricultural fields
are the predominant land use, representing 60% of the total land
area in Henan Province. A double cropping system of winter
wheat (early October–early June) and maize (mid-June–later
September) is the most common planting system used in this
region.

Figure 2. Average annual, maximum, and minimum temperature from 1971 to 2004 in Henan Province, China (A), and (B) average
temperature and rainfall from 1975 to 2006 in different counties within Henan Province, China (B). See Table 1 for key to county name
abbreviations. All these counties were arranged in English alphabetical order.
doi:10.1371/journal.pone.0109188.g002

Collection of crop yield and soil sampling and analysis
Data on total crop production (including wheat, maize and
millet) and wheat yield from 1978–2009 (Figure 3A) were
obtained from the Henan Statistical Yearbook 2010 (13–17)
(http://www.ha.stats.gov.cn/hnjt/index.htm). Annual yield data
for winter wheat and total crop production in 2009 were also
obtained from Henan Statistical Yearbook 2010 (29-7) and the
Agricultural Bureau of each of the 19 counties in which soil
sampling took place (Figure 3B). These counties, along with basic
climatic information, are listed in Table 1. Climatic data of each
county were obtained from Meteorological Bureau of Zhengzhou.
All counties will be referred to by the two-letter codes presented in
Table 1.

The 19 counties were selected as representative of the main
agro-ecosystems of Henan Province. Soil samples were collected
during June 1–15, 2009 following the wheat harvest but prior to
the sowing of maize. Six representative, replicate field plots,
located at least 6 km apart, were selected within each county based on four criteria: (1) the field plots had been continuously cultivated for at least 30 yr with a native variety, (2) the cropland area was located within 5 km of native vegetation with a similar landscape, soil type and texture, and a relatively flat terrain, and (3) all of the sampling sites are privately owned, and (4) there was no potential impact on any endangered or protected species in the sampling site. Geographic coordinates of each sampling site was recorded by handed GPS of Magellan eXplorist 210(USA), and all of these data were attached in the supporting information.

Sample areas of ~1300 m² were established in each plot, with sixteen sampling points taken at random in each of two layers (0–20 cm and 20–40 cm) using a 70 mm - diameter auger. All of the soil samples taken at each layer within a sample plot were mixed together and treated as one sample to represent the value of the plot, yielding 114 soil samples at each layer. Residual plant material was removed from the soil samples after the samples were air-dried at room temperature. The soil samples were then ground to pass a 2 mm sieve, and a portion of the ground sample was subsequently ground again in a porcelain mortar in order to pass through a 0.15-mm sieve. Organic C and total N measurements were obtained from the twice-ground soil samples. Soil organic C (SOC) was measured using a modified Mebius method. Briefly, 0.1 g soil samples were digested for 5 min

![Figure 3. Wheat yield and total crop production (including wheat, maize, millet,) in Henan Province from 1978–2009 (A), and wheat yield and total crop production in different counties within Henan Province in 2009 (B). See Table 1 for key to county name abbreviations.](doi:10.1371/journal.pone.0109188.g003)
The Olsen method was used to determine available soil P. Specific gravity, with any stone material removed and not four layers. Soil porosity was calculated from soil bulk density and density was measured using 100-cm³ soil cores obtained from the three sampling points were used to determine soil bulk density in each plot. Samples were collected separately from four layers in a depth of 0–40 cm in each sampling point. Soil bulk density was measured using 100-cm² soil cores obtained from the four layers. Soil porosity was calculated from soil bulk density and specific gravity, with any stone material removed and not considered in bulk density calculations.

**Calculation of soil organic C and N stores and SOC and TSN**

Total soil organic C store (TSOCS) and total soil N stores (TSNS) at 0–40 cm depth were calculated as follows:

\[
\text{CS} = \sum \text{area}_i \times \text{TSOC}
\]

\[
\text{NS} = \sum \text{area}_i \times \text{TSN}
\]

where \( \text{area} \) is the given total cultivated area of each county, and CS and NS are C and N stores, respectively. SOC and TSN were means of six sampling sites of each county.

### Statistics

Analysis of variance was used to assess the significance of location (county) on soil C and N concentration and storage; means were compared using Duncan’s multi-range test at \( \alpha = 0.05 \). Linear regression was used to determine the relationships between C and N stock versus wheat and total crop production. Principle components analysis was used to assess patterns of similarity/dissimilarity among counties with respect to several environmental variables [21]. All statistical analyses were performed using SPSS 10.0 (Chicago IL, USA).

### Results

Wheat yields increased more than 250% from 1978 to 2009 while total annual crop production in Henan Province increased from 21 to 54 million tons over the same time period (Figure 3A). Wheat yield varied from 143 to 729 thousand tons among the different counties in 2009 (Figure 3B). The absolute value of SOC concentration in the top 40 cm of soil varied from 8.13 to 27.89 g kg⁻¹ among the 19 counties in 2009 (Table 2) while TSN concentration varied from 0.84 to 2.2 g kg⁻¹. Soil C/N varied from 6.4 to 20 (Table 2). Soil organic C stores (TSOCS) in the 0–40 cm soil layer varied from 2,322 g m⁻² to 8,038 g m⁻², whereas total N stores (TSNS) varied from 221 to

Different letters indicate significant differences (p = 0.05) among the 19 counties. Counties are arranged in English alphabetical order.
doi:10.1371/journal.pone.0109188.t002
659 g m\(^{-2}\). The highest value was in XX County and the lowest in LY County in N reserves (Table 3).

Linear regression analysis indicated that total crop production was significantly and positively correlated with SOC and TSN (Figure 4A), soil C and N store (Figure 4B), and soil C and N stocks (Figure 4C). Soil bulk density was significantly and positively correlated with soil N concentration \((r = 0.25, p = 0.008, n = 114)\), soil C \((r = 0.21, p = 0.03, n = 114)\) and N store \((r = 0.43, p = 0.001, n = 114)\). While soil porosity was significantly and negatively correlated with soil N concentration \((r = -0.19, p = 0.05, n = 114)\), soil C \((r = -0.25, p = 0.007, n = 114)\) and N store \((r = -0.32, p = 0.001, n = 114)\).

Principle components analysis revealed that Axis 1, which explained 98% of the variation in all data (eigenvalue = 0.98), was highly correlated with soil C, whereas Axis 2, explaining 1% of the variation (eigenvalue = 0.09), was highly correlated with soil N. Thus, counties such as QX and XP located highly positive on Axis 1 with high levels of soil C, but other counties, such as LK, YJ, and QF, occupied positions toward the negative end of Axis 1 with low soil C (Figure 5).

### Discussion

#### Potential influences on crop yield

It is notable that 14 environmental (e.g., mean annual temperature and precipitation –Table 1) and soil variables (including extractable nutrients–Table 2) examined in our analysis of the data from the 19 counties in Henan Province were correlated with either wheat or total crop yield (data not shown), and total crop production were significantly, positively related to SOC and TSN, soil C and N store, and soil C and N stock (Figure 4). Part of this is likely related to the highly integrated nature of the measures of C and N stocks, i.e., their calculations combine soil concentrations of C and N, soil bulk density, sampling depth, and area of cultivation. However, all of these have been shown to directly influence crop performance. For example, increases in soil C have been shown to increase crop yield in other studies. Lal (2004, 2006) reported increases in yield from 20 to 70 kg ha\(^{-1}\) and 10 to 300 kg ha\(^{-1}\) for wheat and maize, respectively, following increases of 1 MT of C in agricultural soils in Africa [1,8]. Similarly, loss of soil C has been shown to decrease yield in agricultural soils of Canada and the U.S. [4,5].

Soil C-mediated increases of crop yields also may arise from improvements in soil structure and available water-holding

Spatial variation in cultivated soils

In this study, soil organic C concentration averaged 14.9 g kg⁻¹ and total N averaged 1.4 g kg⁻¹ in the 0–40 cm layer across all sites, while soil C and N stores averaged 4.1 kg C m⁻² and 0.38 kg N m⁻², respectively. These values are comparable to published values from other regions of China, including 9–15 g C kg⁻¹ and 1.2–1.8 g N kg⁻¹ in northern China [12,29], and 16.1 g C kg⁻¹ and 1.04 g N kg⁻¹ in eastern and southern China [14,16,30]. Liu et al. (2011) reported soil C stores of 4.57 kg C m⁻² in the Loess Plateau region in northwestern China [13].

Principal components analysis separated the 19 counties primarily along a gradient in soil C, with counties LX, YJ, QF, ZY, TX, and TK (mean soil C = 12.1 g C kg⁻¹) toward the lower end and XP and QX (mean soil C = 20.5 g C kg⁻¹) toward the upper end of Axis 1, which accounted for nearly 80% of the variation in soil and environmental data (Figure 5). Spatial variation in soil organic C in agricultural systems can be influenced by several factors, including microclimate, soil type, topography, and especially human activity [31].

Spatial variation in soil N was essentially orthogonal to that of soil C. This was surprising since typically, the two are highly correlated in terrestrial ecosystems [32]. As a result, the secondary gradient (i.e., Axis 2) was one of soil N, with counties TK, YC, SS, LX, YX, and XP (mean soil N = 1.15 g N kg⁻¹) located toward the lower end of Axis 2 (accounting for <10% of variation) and XX and TY (mean soil N = 1.81 g N kg⁻¹) located toward the upper end of Axis 2 (Figure 5). Although C and N are often correlated through their organic forms in plant detritus, spatial variation of N in soils of agro-ecosystems can also be greatly influenced by the extensive use of N fertilizers.

Management methods used in crop production systems, including tillage practices and fertilizer use, can affect soil C and N on broad spatial scales, including that of an entire Province [33]. Over the course of repeated seasons of crop growth in Henan Province, agricultural fields are repeatedly subjected to soil tillage, planting, fertilization, irrigation, and harvest, all of which potentially influence soil C and N stores [30,34]. In contrast, Zhang et al. (2012) reported that raised-bed planting, a viable alternative to conventional tillage, can significantly enhance the yield of summer maize while simultaneously improving soil structure, as well as the structure and function of microbial communities essential to the quality of agricultural soils [22].

Results presented in the current study underscore the complexity of factors that can impact agricultural soils and their ability to produce crops to meet the ever-increasing demand in China resulting from population growth. Some of the spatial pattern exhibited in ordination space (Figure 5) is clearly related to regional factors, such as microclimate. For example, WY and LC are adjacent to each other in Henan Province (Figure 1) and are also closely clustered in ordination space, indicating that they are very similar with respect to environmental and soil characteristics. XP and SS, however, are also adjacent counties; yet occur distant from each other in ordination space, indicating great dissimilarity in environmental and soil factors. Agronomists should take into account the large spatial variability in important components of the soils in Henan Province, especially in the variation of soil C and N, when considering appropriate agronomic management practices.
