ABSTRACT
We continue our investigation of particle acceleration in the pulsar equatorial current sheet (ECS). Our basic premise has been that the charge carriers in the current sheet originate in the polar caps as electron–positron pairs, and are carried along field lines that enter the ECS beyond the magnetospheric Y-point. In this work, we investigate further the charge replenishment of the ECS. We discovered that the flux of pairs from the rims of the polar caps cannot supply both the electric charge and the electric current of the ECS. The ECS must contain an extra amount of positron (or electronic depending on orientation) electric current that originates in the stellar surface and flows outwards along the separatrices. We develop an iterative hybrid approach that self-consistently combines ideal force-free electrodynamics in the bulk of the magnetosphere with particle acceleration along the ECS. We derive analytic approximations for the orbits of the particles, and obtain the structure of the pulsar magnetosphere for various values of the pair formation multiplicity parameter $\kappa$. For realistic values $\kappa \gg 1$, the magnetosphere is practically indistinguishable from the ideal force-free one, and therefore, the calculation of the spectrum of high energy radiation must rely on analytic approximations for the distribution of the accelerating electric field in the ECS.

Key words: magnetic fields – relativistic processes – pulsars: general.

1 INTRODUCTION
We continue our investigation of electromagnetic (Poynting) energy dissipation in the axisymmetric pulsar magnetosphere following the ‘hybrid’ approach of Contopoulos (2007a,b), Contopoulos, Kazanas & Kalapotharakos (2014), Contopoulos (2019, hereafter Paper I), and Contopoulos & Stefanou (2019, hereafter Paper II). The pulsar magnetosphere is considered to be everywhere ideal and force-free except in a dissipative layer that develops beyond the tip of the closed line region along the equatorial current sheet (ECS). The ECS is threaded by magnetic field lines that originate around the rim of the polar cap and contain a finite amount of magnetic flux,

$$\Psi_{ECS} = 2\pi r_{pc} \delta B_\ast = \frac{2A}{r_{pc}} \Psi_{open} \ll \Psi_{open} = \pi r_{pc}^2 B_\ast.$$ (1)

Here, $\Psi_{open} \equiv 1.25 \Psi_{open dipole}$ is the total amount of magnetic flux that crosses the light cylinder at a distance $r_{pc} \equiv c/\Omega$, $\Psi_{open dipole} \equiv \pi r_{pc}^2 B_\ast / r_{pc}$ is the amount of dipole magnetic flux that crosses the equator beyond the light cylinder (Contopoulos, Kazanas & Fendt 1999; Spitkovsky 2006; Timokhin 2006). $r_{pc} \approx \sqrt{1.25 r_{pc} / \Omega}$ is the radius of the so-called ‘polar cap’, and $\Omega$ is the angular velocity of stellar rotation. These magnetic field lines carry the electrons and positrons required to support the electric current of the ECS, and transfer electromagnetic energy from the central ‘generator’ (the stellar rotation) to the electrons and positrons in the ECS. The thickness $\delta$ of the polar cap rim that supplies the ECS with charge carriers and electromagnetic energy is inversely proportional to the pair formation multiplicity $\kappa \gg 1$ (how many pairs are produced per Goldreich–Julian charge particle in the polar cap; Papers I and II). Without loss of generality, we will only consider aligned rotators with $B$ along $\Omega$ at the poles.

In our ‘hybrid’ approach, particle orbits are only considered in the dissipative ECS where positrons are accelerated outwards and electrons inwards. Electrons and positrons are in general extremely relativistic (Lorentz factors $\gg 1$), and, during their acceleration by the radial electric field that develops in the ECS, they both radiate high energy radiation along the direction of their motion. There is no point to follow their motion in the rest of the ideal magnetosphere where they simply flow along magnetic field lines and drift across them with drift velocity $cE \times B/B^2$ and gyroradii much smaller than the macroscopic dimensions of...
the magnetosphere. The main reason we opted for this 'hybrid' approach (ideal force-free everywhere with consideration of particle dynamics only in the ECS) is that we believe it is too early for an ab initio reconstruction of the pulsar magnetosphere with Particle-in-Cell (PIC) numerical simulations (Contopoulos 2016). This is due to insufficient numerical resolution (a few hundred grid points inside the light cylinder is grossly inadequate as has been shown clearly in fig. 1 of Tchekhovskoy, Spitkovsky & Li 2013) and unphysical simulation parameters (Larmor radii on the order of the light cylinder radius instead of at least nine orders of magnitude smaller, Lorentz factors smaller than about 10^3 instead of at least five orders of magnitude larger, etc.). Moreover, it is not clear whether the dissipation obtained with present day numerical PIC codes (∼30 per cent of \(E\) within a few \(r_{\text{lc}}\) just outside the light cylinder) is indeed physical (as e.g. in Contopoulos et al. 2014) or numerical (compare e.g. fig. 6 of Cerutti et al. 2015 with fig. 13 of Parfrey, Beloborodov & Hui 2012 and fig. 1c of Tchekhovskoy et al. 2013). This makes them inadequate to study the physical electromagnetic energy dissipation without a deeper understanding of the physical processes that take place in that region.

In this work, we will improve the 'ring-of-fire' model proposed in Paper II. In that model, we had assumed for simplicity that the dissipation layer (denoted by DL in that paper) had a finite radial extent at the origin of the ECS beyond the tip of the closed-line region near the light cylinder. Beyond that region, the ECS was considered dissipationless all the way to infinity. We will now relax that assumption since it seems more natural that the ECS is everywhere dissipative.

## 2 Supply of Pairs

The dissipation layer extends from the tip of the closed-line region at \(r \approx r_{\text{lc}}\) to infinity, i.e. the dissipation layer and the ECS are one and the same. This is a natural way to connect the region of flux \(\Psi_{\text{ECS}}\) with the force-free electrodynamics (FFE) solution outside (see Fig. 1). In the limit that \(\Psi_{\text{ECS}} \ll \Psi_{\text{open}},\) the solution must be almost indistinguishable from the dissipationless FFE solution of Contopoulos et al. (1999) with a very narrow region between the last open field lines and the separatrix and ECSs. Notice that Fig. 1 and the lower subfigures in Fig. 4 below are consistent with most 'ab initio' PIC simulations in the literature that show extended magnetic field lines near the light cylinder. Beyond that region, the ECS was considered dissipationless all the way to infinity. We will now relax that assumption since it seems more natural that the ECS is everywhere dissipative.

### 2.1 Supply of Pairs

The ECS contains a radial electric current, \(I_{\text{ECS}}\), a distribution of surface electric charge density \(\sigma\), and is threaded by a finite amount of magnetic flux \(\Psi_{\text{ECS}}\). The magnetosphere just above the ECS contains a radial electric current, \(E_r = -x B_z\), and a tangential magnetic field \(E_\theta = x B_r = 2\pi r \sigma\). The ECS contains a radial electric current, \(I_{\text{ECS}}\), a distribution of surface electric charge density \(\sigma\), and is threaded by a finite amount of magnetic flux \(\Psi_{\text{ECS}}\). The magnetosphere just above the ECS contains a radial electric current, \(E_r = -x B_z\), and a tangential magnetic field \(E_\theta = x B_r = 2\pi r \sigma\).

\[
B_\theta = \frac{I_{\text{ECS}}}{x r_{\text{lc}} c}
\]

We have introduced here the notation \(r/r_{\text{lc}} = x\). As we discussed in Paper I of this series, the magnetic field lines that enter the equatorial dissipation layer carry a total flux of electron–positron pairs (number of electron–positron pairs that enter the ECS per unit time and unit area) equal to \(2 n_{\text{pairs}} v_p = 2 n_{\text{pairs}} (B_r/B_\theta)\), where \(v_p\) and \(v_z\) are the poloidal and vertical component of the pair velocity, \(n_{\text{pairs}}\) is the number density of pairs, and \(B_r/B_\theta\) is the poloidal magnetic field. The extra factor of 2 is due to the two contributions from above and below the equatorial plane. These magnetic field lines originate on the polar cap, where the pairs are generated and outflow at close to the speed of light. Conservation of the pair flux implies that

\[
\frac{n_{\text{pairs}} v_p}{B_p} = \frac{n_{\text{pairs}} v_p}{B_\theta} \approx \frac{\kappa\Omega}{2\pi e c}\]

Here, \(\Omega_{B_r/(2\pi c)} \equiv \rho_{\text{GJ}}\) is the Goldreich–Julian charge density at the polar cap, and \(e\) is the electron/positron charge. This is the only source of charges in the dissipation layer, then the surface charge density \(\sigma\) at some distance \(r\) in the dissipation layer is equal to the sum of the positive surface charge density \(\sigma_+\) carried by the positrons that enter the dissipation layer inside distance \(r\) and move outwards towards \(r\) and the negative surface charge density \(\sigma_-\) carried by the electrons that enter outside distance \(r\) and move inwards towards \(r\).

\[
\rho_{\text{GJ}} = \int_{r}^{\infty} r dr' n_{\text{pairs}} v_{z} \approx \frac{\kappa \Omega}{2\pi e c} \int_{r}^{\infty} r dr' n_{\text{pairs}} v_{z}
\]

We have assumed that there are more pairs than primary particles in these field lines, i.e. that \(\kappa \gg 1\). This allows us to ignore the electric current carried by the primary particles. In a future publication, we will generalize our analysis in the limit \(1 \geq \kappa \geq 0\).
This very interesting numerical result has never before been pointed out in the literature.\textsuperscript{3} Reversing equation (9) and using equation (10) above, we obtain the amount of magnetic flux $\Psi_{\text{ECS}}$ along the rim of the polar cap that contains the electric charges needed in the ECS, namely

$$
\Psi_{\text{ECS}} = \frac{2\delta}{r_{pc}} \Psi_{\text{open}} = \frac{\pi I_{\text{ECS}}}{2k\Omega} \approx \frac{\Psi_{\text{open dipole}}}{4k} \approx \frac{\Psi_{\text{open}}}{5k}.
$$

This relation allows us to obtain the thickness $\delta$ of the rim of the polar cap, namely

$$
\delta \approx \frac{r_{pc}}{10k}.
$$

Note that the above detailed considerations yielded a correction in the expression for $\delta$ with respect to the one in Paper I (equation 9).

### 3 PARTICLE ORBITS IN THE ECS

Let us now consider the motion of electrons and positrons at the mid-plane of the dissipation layer beyond the light cylinder. Electrons and positrons do not just move radially. They move very close to the speed of light, but they are also deflected in the azimuthal direction together with the overall pulsar rotation. At the mid-plane, $B_\theta = 0$ and $E = E_z = x|B_x| > |B_z| = B$. The total electromagnetic force acting on the positrons in the mid-plane is equal to

$$
e(E_\hat{r} + |v|B_\hat{v} \times \hat{z}/c) \approx e(E_\hat{r} + B_\hat{v} \times \hat{z})
$$

(13)

(vectors with hats denote unit vectors along them). For an extremely relativistic particle with $|v| \approx c$, the total electromagnetic force must be equal to

$$
m_e \frac{d\Gamma/v}{dt} = m_e \frac{d\Gamma}{dt} \hat{v} + m_e \frac{\Gamma c^2}{R_e} \hat{v}_\perp.
$$

(14)

The second term in the above expression is the centrifugal force. Here, $R_e$ is the radius of curvature of the particle orbit in the equatorial plane, and $\hat{v}_\perp \equiv \hat{v} \times \hat{z}$ is the unit vector away from the centre of the instantaneous circular orbit. We will henceforth make the approximation that the instantaneous radius of curvature is so large that the centrifugal force term is much smaller than the parallel acceleration term. Decomposing equation (13) along $\hat{v}$ and $\hat{v}_\perp$ we obtain

$$
e(E_\hat{r} + B_\hat{v} \times \hat{z}) = e E_\hat{r} \hat{v} + e(E_\hat{r} \cdot \hat{v}_\perp) + B_\hat{v}_\perp.
$$

(15)

The expressions in equations (15) and (14) must be equal to each other, and therefore, the term along $\hat{v}_\perp$ must almost vanish. Thus, $E_\perp + B_\perp \approx 0$, and since $E_\perp = E_x \cos \alpha = -xB_z \cos \alpha$, we obtain

$$
\cos \alpha = \frac{1}{x}.
$$

(16)

\textsuperscript{3} As is well known since Contopoulos et al. (1999), the electric current distribution along open magnetic field lines has a maximum value near the maximum electric current of a split monopole magnetic field configuration with the same amount of open magnetic flux $\Psi_{\text{open}}$—namely $\Omega \Psi_{\text{open}}/(2\pi)$.

Beyond that maximum, the magnetosphere contains a region of distributed return electric current near the equator. We now point out for the first time that the amount of distributed return electric current is such that the remaining return current that flows along the ECS is equal to $\Omega \Psi_{\text{open dipole}}/(2\pi)$, and not $\Omega \Psi_{\text{open dipole}}/(2\pi)$ as would be naively expected from the analogy with a split monopole configuration. As $\kappa$ decreases, the amount of distributed return electric current increases.

\newpage

Figure 2. Detail of the magnetospheric replenishment of the electric current and electric charge in the ECS near the tip of the closed-line region for the solution shown in Fig. 1. Neighbouring $\Psi$ lines differ by 0.01$\Psi_{\text{open dipole}}$. Grey/green/blue arrows: pairs/electrons/positrons, respectively. What is not shown here is the extra postironic electric current component that flows along the separatrix and the ECS (equation 7).

Here, $v_{p+}/v_{p-}$ are the radial velocity of the positrons/electrons in the ECS, respectively, and as we will see below, $v_{p+} \equiv |v_{p+}| \approx -v_{p-}$ at every position along the mid-plane. Equation (6) has one major flaw: as $r \rightarrow r^*_c$, $\sigma$ does not approach zero as it should (Timokhin 2006). The only way to reconcile this discrepancy is to introduce an extra outward flow of positrons through the separatrix and ECSs equal to

$$
I_{\text{ECS separatrix}} = 4\pi e \int_{r_c}^{r_\infty} r' \, dr' n_{\text{pairs}} |v_{\perp}|.
$$

(7)

This electric current component of the ECS may be due to electron–positron pairs that outflow along the separatrix, and when they reach the Y-point, the positrons outflow along the ECS, and the electrons flow back to the star along the separatrices. We will discuss the physical significance of this extra electric current component in a forthcoming publication. Adding the above component to equation (6) we obtain our final expressions for the equatorial electric current density and the total equatorial electric current, namely

$$
\sigma = \sigma_+ + \sigma_- + I_{\text{ECS separatrix}} \frac{2\pi r |v_{\perp}|}{n_{\text{pairs}}},
$$

(8)

$$
I_{\text{ECS}} \approx 2\pi r |v_{\perp}| (\sigma_+ - \sigma_-) + I_{\text{ECS separatrix}}
$$

$$
= 4\pi e \int_{r_c}^{r_\infty} 2\pi r' dr' n_{\text{pairs}} |v_{\perp}|,
$$

(9)

$$
= 4\pi e \int_{r_c}^{r_\infty} 2\pi r' dr' \left(\frac{n_{\text{pairs}} v_p}{B_p}\right) |B_z|
$$

$$
= 4\pi \kappa \Omega \int_{r_c}^{r_\infty} 2\pi r'^2 dr' |B_z|
$$

$$
= \frac{2\pi \kappa \Omega}{\pi} \Psi_{\text{ECS}}.
$$

(10)

Furthermore, Contopoulos et al. (1999), Spitkovsky (2006), and Timokhin (2006) obtained numerically that

$$
I_{\text{ECS}} \approx \frac{\Omega \Psi_{\text{open dipole}}}{2\pi} = \frac{1}{2} \Omega B_r r_{pc}^2.
$$

(11)
Here, \( \alpha \) is the angle between the azimuthal direction \( \phi \) and the direction of particle motion \( \hat{\mathbf{r}} \). We remind the reader that, beyond the light cylinder, \( E > 0 \) in the equatorial plane. Similar considerations apply to the electrons in the ECS. From the above, one can easily show that

\[
|v_r| = |v| \sin \alpha \approx \frac{\sqrt{x^2 - 1}}{x} c, \tag{17}
\]

\[
v_\phi \equiv |v| \cos \alpha \approx \frac{1}{x} c. \tag{18}
\]

With the above two equations, we reach the following unexpected result: after the electrons and positrons enter the ECS, they follow straight lines that are tangent to the light cylinder! The positrons travel outwards, whereas the electrons travel inwards. Both travel in the direction of pulsar rotation (see Fig. 3 for details). The closer we are to the light cylinder, the more azimuthal the orbits, and the further away, the more radial they are. Straight lines have an infinite radius of curvature, and therefore, equations (17) and (18) are exact. It would be nice to check whether particle trajectories in the ECS are also along straight lines in PIC numerical simulations (e.g. Cerutti, Philippov & Spitkovsky 2016; Kalapotharakos et al. 2018).

The raison d’être of the above discussion is that we prefer to avoid the complex integration of the Speiser-like orbits that the particles follow when they enter the ECS (Speiser 1965, see Paper II). After all, as the particles gain energy, they are confined more and more towards the mid-plane of the ECS where \( B_\phi = 0 \). We thus ignored the meandering motion due to the azimuthal component of the magnetic field \( B_\phi \), in a guiding centre-type approximation. In a forthcoming publication, when we will consider the effect of radiation reaction in the particles’ motion, we will need to evaluate the radius of curvature of the meandering particle trajectory.

Putting everything together and differentiating equation (8) we obtain

\[
\begin{align*}
\frac{d}{dr}(r|v_r|\sigma) &= \frac{d}{ds}(\sigma \sqrt{x^2 - 1} c) = 4\pi n_{\text{pairs}} v_r |v_r| \\
&= 4\pi n_{\text{pairs}} v_\phi (B_z |/B_\phi) = \frac{2\pi}{\pi} \left| B_z \right|.
\end{align*}
\tag{19}
\]

Solving for the distribution of \( B_z \) along the dissipation layer, and remembering that \( \sigma = E_\phi / (2\pi) = x B_z / (2\pi) \) yields

\[
B_z = \frac{1}{4\pi x} \frac{d}{dx} \left( x \sqrt{x^2 - 1} B_z \right). \tag{20}
\]

Notice that \( B_z \) is negative. The latter simple result is the basis of the hybrid approach proposed below that yields the ideal force-free magnetosphere with a realistic dissipative equatorial boundary condition.

### 4 HYBRID NUMERICAL METHOD

The new element of this work is that the ECS and the dissipation layer are one and the same (or in other words that the magnetic flux \( \Psi_{\text{ECS}} \) from the rim of the polar cap is distributed all along the ECS). The realization that the ECS is not dissipationless modifies the global solution in a subtle way. We propose the following iterative numerical approach that allows us to obtain a self-consistent global solution that is ideal force-free everywhere except in the ECS.

(i) We use the solver introduced in Contopoulos et al. (1999) to solve the pulsar equation. This allows us to obtain the unique axisymmetric ideal force-free magnetospheric solution that crosses the light cylinder smoothly for a particular equatorial boundary condition beyond the light cylinder (see also e.g. Contopoulos 2007a,b).

(ii) We obtain first the dissipationless solution of Contopoulos et al. (1999) (the so-called CKF solution) by setting \( \Psi = \Psi_{\text{open}} \) along the equator beyond the light cylinder, and iteratively adjusting the value of \( \Psi_{\text{open}} \). This solution contains a dissipationless equatorial return current sheet connected to two separatrix return current sheets at the Y-point that develops at the tip of the corotating closed-line region.

(iii) From the solution, we obtain the distribution of \( B_z \), just above the ECS. Then, according to equation (20),

\[
\Psi(r \geq r_\text{lc}) = \Psi(r_\text{lc}) + \int_{r_\text{lc}}^r 2\pi B_z \, r \, dr' = \Psi_{\text{open}} - \frac{\pi r_\text{lc}^2}{2\kappa} x \sqrt{x^2 - 1} B_z. \tag{21}
\]

---

\(^4\)Note added in proof: these are the same as the components of the so-called `Aristotelian' speed of light velocities for electrons and positrons in the ECS postulated by Gruzinov (2012).
(iv) Given this new Dirichlet-type boundary condition along the ECS, we solve again the pulsar equation above the ECS. This yields a new $B_r$ distribution.

(v) We repeat the above steps (iii) and (iv) till the solution relaxes to a steady-state configuration in which both the electric current and the electric charge of the ECS are accounted for self-consistently, and equation (19) is satisfied everywhere along the ECS.

We implemented the above numerical method and obtained the global magnetospheric structure of an aligned pulsar rotator for various values of the pair formation multiplicity parameter $\kappa \geq 1$ (Fig. 4). Each iteration runs on a $200 \times 200$ spatial numerical grid and takes about 1 h to converge. The stellar dipole boundary condition is imposed in the central circle of radius 0.1 $r_{lc}$.

The separatrix return current sheet has a width of about 0.05 inside the red lines of Figs 1, 2, and 4. For $\kappa \geq 40$, the solution is almost indistinguishable from the ideal solution of Contopoulos et al. (1999). In that case, the calculation of dissipation, particle acceleration, and high energy radiation can only be based on analytical approximations of the equatorial electric and magnetic fields (see equations 22–25 below). Notice that our analysis is valid for $\kappa \geq 2$ since below that value, our approximation that $\Psi_{ECS} = (5x)^{-1} \Psi_{open} \ll \Psi_{open}$ breaks down. We also calculated the outgoing Poynting flux integrated over a sphere of radius $x$ as a function of radius for various values of $\kappa$ (Fig. 5). Most dissipation takes place within about 2 light cylinder radii from the light cylinder, and exceeds a few tens of per cent of $\dot{E}$ only for pulsars with extremely low pair formation multiplicity.

Notice the similarity between case $\kappa = 1$ in Fig. 4 and case $f_{inj} = 1$ in fig. 3 of Cerutti et al. (2015), as well as between Fig. 5 and fig. 6 of that paper. This similarity is by itself very interesting. It implies that global PIC simulations with the lowest possible (numerically) amount of dissipation shown in the literature (e.g. Cerutti et al. 2016; Kalapotharakos et al. 2018) are very similar to our dissipative solutions that describe pulsars with very low pair formation multiplicities $\kappa \approx 1$, not young pulsars with $\kappa \gg 1$. This confirms our concern that ab initio numerical simulations are presently inadequate to study the physical electromagnetic energy dissipation in the pulsar magnetosphere. Our hybrid method, however, allows us to have better control over the numerical dissipation since the bulk of the magnetosphere is by construction ideal, and dissipation is restricted to the ECS. This is why we are able to run simulations with extremely low dissipation and very high $\kappa$ values.

5 USEFUL APPROXIMATIONS

In young pulsars with high pair formation multiplicity $\kappa \gg 1$, the distribution of $B_r$ just above the ECS that we obtained numerically with the above procedure may be approximated by the expression

$$B_r \approx \frac{1}{x^2} \left(1 - \frac{1}{x^2}\right)^{0.7} B_{lc\; dipole}. \quad (22)$$

Here, $B_{lc\; dipole} \equiv B_{ratura}^d/(2 r_{lc}^3)$ is the equatorial value of the vacuum dipole magnetic field at the light cylinder. Therefore, according to equations (2) and (20),

$$B_r \approx \frac{3}{5 K x^3} \left(1 - \frac{1}{x^2}\right)^{0.2} B_{lc\; dipole}. \quad (23)$$

$$E_r \approx \frac{3}{5 K x^3} \left(1 - \frac{1}{x^2}\right)^{0.2} B_{lc\; dipole}. \quad (24)$$

Notice the very sharp decrease of $B_r$ and $E_r$ with distance. Finally, let us also introduce

$$B_\phi = \frac{I_{ECS}}{r_{lc} c} \approx \frac{\Omega_2 r_{lc}^2 B_s}{2 x r_{lc}} = - \frac{B_{lc\; dipole}}{x}. \quad (25)$$

This is a nice simple result that derives from equation (9). We can now obtain analytically the distribution of electromagnetic (Poynting) flux that enters the ECS, namely

$$\dot{E}_{ECS} = 2 \int_{x=1}^{x} 2 \pi r_{lc}^2 \frac{c}{4 \pi} E_r |B| \; dx$$

$$= \frac{I_{ECS}}{2 \pi r_{lc}} \int_{x=1}^{x} 2 \pi r_{lc}^2 E_r |B| \; dx$$

$$\approx \frac{I_{ECS} \Psi_{ECS}}{2 \pi r_{lc}} \left(1 - \frac{1}{x^2}\right)^{1.2}$$

$$\approx \frac{6}{25 \kappa} \dot{E} \left(1 - \frac{1}{x^2}\right)^{1.2}. \quad (26)$$

The factor of 2 in equation (26) takes into account the fact that both hemispheres emit Poynting flux. Here, $\dot{E} \approx (2/3) \Omega^2 (\Psi_{open}/2\pi^2)^2/c$ is the total electromagnetic spin-down energy loss rate (Contopoulos & Spitkovsky 2006). Equivalently, the outgoing Poynting flux integrated over a sphere of radius $r$ is equal to

$$\dot{E}_{\text{Poynting}}(x) = \dot{E} - \dot{E}_{ECS}(x)$$

$$\approx \begin{cases} 
\dot{E} \left(1 - \frac{6}{25 \kappa} \left(1 - \frac{1}{x^2}\right)^{1.2}\right) & \text{if } x \geq 1, \\
\dot{E} & \text{otherwise}. 
\end{cases} \quad (27)$$

As we can see in Fig. 5, the fits are almost perfect for $\kappa \gg 2$, and break down for $\kappa \leq 1$. Most of the particle acceleration and consequent radiation in the ECS take place very close to the light cylinder, hence the justification of the term ‘ring-of-fire’ introduced in Paper II.

Up to now, we have assumed that the pair formation multiplicity $\kappa$ is very high. However, in order to attain observed dissipation efficiencies on the order of 1–10 per cent, we need $\kappa$ values on the order of 10–2. We suspect that these are not typical values for the bulk of the polar cap, and that $\kappa \to 0$ as we approach the edge of the polar cap along the separatrices between field lines that close inside and outside the light cylinder. This idea certainly needs further investigation.

6 CONCLUSION

In this series of three papers, we associate the magnetospheric dissipation with the ‘struggle’ of the magnetosphere to supply the electric charges required to support the electric charge and the electric current of the ECS. During our self-consistent investigation we discovered that the supply of pairs from the rims of the polar caps is not sufficient. The ECS requires an extra amount of positronic electric current that originates in the stellar surface and flows outwards along the separatrices. We will discuss the physical significance of this extra positronic electric current in a forthcoming publication.

The hybrid numerical method presented in this work allows us to study the magnetospheric dissipation in a realistic pulsar magnetosphere at a level never before being possible with standard numerical simulations (field calculations and ab initio PIC calculations). We have obtained analytical expressions for the distribution of dissipation along the ECS as a function of the pair formation multiplicity $\kappa$. As shown also in several previous works, magnetospheric dissipation indeed takes place within a couple of...
Figure 4. Magnetospheric structure for various values of $\kappa \gtrsim 1$. $\eta \equiv \dot{E}_{\text{ECS}}/E$ is the corresponding dissipation efficiency. Red line: separatrix. Lines as in Fig. 1. Clockwise from top left: $\kappa = \infty$, 40, 4, 1, 2, 8.
Hybrid simulations

Figure 5. Outgoing Poynting flux integrated over a sphere of radius $x$ as a function of radius for various values of $\kappa$ (black lines) and corresponding analytical fits according to equation (27) (red lines). Energy flux normalized to the spin-down power of an aligned pulsar without dissipation (CKF solution; blue line). Most dissipation takes place within about 2 light cylinder radii from the light cylinder, and exceeds 20 per cent of $\dot{E}$ only for pulsars with very low pair formation multiplicity.

light cylinder radii beyond the tip of the closed-line region at the light cylinder, hence the name 'ring-of-fire' introduced in Paper II of this series.

The analytical expressions for $B_z$ and $E_r$ in the ECS that we derived above allow us to calculate directly not only the distribution of dissipated electromagnetic energy, but also the detailed outward acceleration of the positrons and the inward acceleration of the electrons in the ECS in the presence of radiation reaction. For the particular straight line motion along the ECS discussed in Section 3 above, if we consider the radius of curvature $R_c$ of the meandering motion above and below the equator, the force balance equation along the instantaneous direction of motion in the presence of radiation reaction (equation 14, Paper I) becomes

$$\frac{d\Gamma}{dx} = \frac{e B_c \gamma_{\text{dc}}}{m_e c^2} \left\{ \frac{3}{5 \kappa x} \left(1 - \frac{1}{x^2}\right)^{0.2} - \frac{\Gamma^4 / \Gamma_{\text{nl}}}{(R_c / \gamma_{\text{dc}})^4} \left(1 - \frac{1}{x^2}\right)^{-0.5} \right\}. \quad (28)$$

Here, $\Gamma_{\text{nl}} = (3r_e^2 B_c / 2e)^{1/4} = 4 \times 10^7 (B_c / 10^{13} \text{G})^{1/4} (P / 1 \text{s})^{-1/4}$, and $P$ is the pulsar period. The integration of equation (28) will yield the spectrum of the emitted $\gamma$-ray radiation, and will be performed in a forthcoming publication.

ACKNOWLEDGEMENTS

IC and JP would like to acknowledge support from the International Space Science Institute ISSI in Bern. PS would like to acknowledge support from PHAROS COST Action CA16214 for a short-term scientific mission at the Observatoire Astronomique de Strasbourg in 2019 July–August.
