ABSTRACT

We present the results of an halo occupation distribution (HOD) analysis of star-forming galaxies at $z \sim 2$. We obtained high-quality angular correlation functions based on a large sgzK sample, which enabled us to carry out the HOD analysis. The mean halo mass and the HOD mass parameters are found to increase monotonically with increasing $K$-band magnitude, suggesting that more luminous galaxies reside in more massive dark haloes. The luminosity dependence of the HOD mass parameters was found to be the same as in the local Universe; however, the masses were larger than in the local Universe over all ranges of magnitude. This implies that galaxies at $z \sim 2$ tend to form in more massive dark haloes than in the local Universe, a process known as downsizing. By analysing the dark halo mass evolution using the extended Press–Schechter formalism and the number evolution of satellite galaxies in a dark halo, we find that faint Lyman break galaxies at $z \sim 4$ could evolve into the faintest sgzKs ($22.0 < K \leq 23.0$) at $z \sim 2$ and into the Milky-Way-like galaxies or elliptical galaxies in the local Universe, whereas the most luminous sgzKs ($18.0 < K \leq 21.0$) could evolve into the most massive systems in the local Universe. The stellar-to-halo mass ratio (SHMR) of the sgzKs was found to be consistent with the prediction of the model, except that the SHMR of the faintest sgzKs was smaller than the prediction at $z \sim 2$. This discrepancy may be attributed that our samples are confined to star-forming galaxies.

Key words: cosmology: observations — dark matter — galaxies: evolution — galaxies: formation — large-scale structure of universe — surveys

1 INTRODUCTION

It is well known that galaxies are formed in highly dense regions of dark matter, termed dark haloes. According to the ΛCDM model, the large-scale structure of the Universe seen today originated from small density fluctuations of the dark matter in the early Universe. Galaxies are thought to have formed from cool gases trapped in the gravitational wells of the dark matter.

Galaxy clustering is one of the most important keys to unveiling the galaxy evolution through cosmic time. The clustering amplitude of galaxies increases monotonically with the halo mass; i.e., more massive dark haloes are more strongly clustered.

Many previous studies have revealed that galaxy clustering, which provides a measure of the dark halo mass, depends on the physical properties of galaxies; i.e., the brightness (Zehavi et al. 2003), the star-formation rate (SFR; Béthermin et al. 2014), morphology (Zehavi et al. 2002), and colour (Zehavi et al. 2003, 2005, 2011; Coil et al. 2008). Because of recent galaxy selection methods that allow us to obtain large numbers of distant galaxies effectively, such as the dropout method (e.g., Madau et al. 1996; Steidel et al. 1996) and the multi-colour selection method (e.g., Franx et al. 2003; Daddi et al. 2004), the clustering properties of the distant Universe have been described (e.g., Steidel et al. 1996; Ilbert et al. 2006; Ilbert et al. 2006; Ilbert et al. 2006; Ilbert et al. 2006; Ilbert et al. 2006), as well as those of the local Universe (e.g., Zehavi et al. 2003; Zheng et al. 2007). It is important to investigate the clustering evolution of galaxies with different physical properties to gain insight into galaxy evolution. Al-
though galaxy formation, the complex baryonic processes that occur within dark haloes mean that galaxy evolution is not straightforward.

The “halo occupation distribution” (HOD, e.g., Ma & Fry 2000; Peacock & Smith 2000; Seljak 2000; Berlind & Weinberg 2002; Berlind et al. 2003) is a powerful theoretical approach that relates the galaxy distribution to the dark matter distribution. The HOD formalism describes the galaxy distribution within the host dark halo by characterizing them from the perspective of the probability distribution $P(N|M)$ that a halo of virial mass $M$ contains $N$ galaxies with specific physical properties, such as colour or galaxy type. One of the advantages of the HOD formalism is that the HOD parameters have explicit physical meanings; this enables us to easily interpret the relationship between the galaxies and the host haloes.

The largest difference between the HOD framework and other galaxy-halo correspondence methods, such as the abundance matching method (e.g., Seljak 2000; Cooray & Sheth 2002), is that the HOD model is based on a more realistic halo model and does not assume a one-to-one correspondence between galaxies and haloes. It is known that different types of galaxy pairs contribute to the two-point angular correlation function (ACF) between large-angular scales and small-angular scales. At the small-angular scale, galaxy clustering is contributed to mainly by galaxy pairs that are located in the same dark halo, referred to as the “1-halo term”, whereas galaxy clustering at the large-angular scale is attributed to galaxy pairs that reside in different dark haloes, referred to as the “2-halo term”. These two components result in different power-law slopes of the ACF at the two angular scales; these characteristics are well described using the HOD formalism.

HOD analyses have been successful in revealing the clustering properties of galaxies and the characteristics of the host haloes both in the local Universe (e.g., Zehavi et al. 2003; 2011; Zheng et al. 2003; 2004; Matsuoka et al. 2011;Coupon et al. 2012) and the distant Universe (e.g., Hamana et al. 2004; 2006; Jose et al. 2013; Béthermin et al. 2014; Durkalec et al. 2014; McCracken et al. 2013; Martinez-Manso et al. 2013; Zehavi et al. 2003; 2011) carried out HOD analyses of the numerous local SDSS galaxies (~ 700,000 galaxies over 8,000 deg$^2$) to investigate the luminosity and colour dependence of the clustering of galaxies. Zehavi et al. (2011) found that the clustering strength of the galaxies increased slowly at a luminosity of $L < L_*$ and increased rapidly at $L > L_*$. Moreover, Zehavi et al. (2011) found that the ACF of red galaxies has a strong clustering strength and steeper slope than that of blue galaxies, and faint red galaxies exhibit remarkably strong clustering at the small scale, which is comparable to the most luminous red galaxies. In the distant Universe, Hamana et al. (2004) calculated the mean dark halo mass and the expected number of galaxies within a dark halo at $z \sim 4$, and discussed an evolutionary relation between the Lyman break galaxies (LBGs) at $z \sim 4$ and the old passively evolving galaxies (OPEGs) at $z \sim 1$. Recently, Durkalec et al. (2014) implemented an HOD analysis of spectroscopically confirmed galaxies at $2.0 < z < 5.0$, and discussed galaxy evolution from high-z to the local Universe. However, there have been few HOD analyses of $z \sim 2$ galaxies, due to difficulties in collecting a large sample of galaxies. Wide-field near infra-red (NIR) observations are required for a large sample of $z \sim 2$ galaxies; however, this is difficult because of the poor sky transparency and the limitations of the physical size of NIR detectors. Béthermin et al. (2014) carried out an HOD analysis on sBzK galaxies in the COSMOS field; however, the calculations of the dark halo mass were not sufficiently accurate due to the large errors of ACFs at large angular scales.

The relationship between the spatial distribution of galaxies and the underlying invisible dark matter density field is known as galaxy bias, $b_g$. The HOD formalism can relate the dark halo and galaxy bias by comparing the ACFs determined from the assumed halo model and observation.

Another method that can be used to relate the dark halo to the distribution of baryons in the dark halo is termed the “stellar-to-halo mass ratio” (SHMR). The SHMR has been the subject of many studies aiming to reveal or constrain the properties of galaxies and the conversion efficiency from baryons to galaxies in dark haloes (e.g., Behroozi et al. 2011; 2013; Moster et al. 2010; Yang et al. 2012; Leauthaud et al. 2012). On the $M_h$ versus $M_*$ diagram, the SHMR has a peak at $M_h \sim 10^{12} M_\odot$, which corresponds to the most efficient mass (pivot halo mass) to convert from baryonic matter to stars, which is consistent with theoretical prediction (e.g., Blumenthal et al. 1984); however, SHMR at the peak halo mass is much smaller than the universal baryon fraction ($\Omega_b/\Omega_m \sim 0.167$) (e.g., Behroozi et al. 2011; Leauthaud et al. 2012; Yang et al. 2012). This characteristic dark halo mass is determined by the equilibrium of the suppression mechanism that star-formation becomes equal between the shallow gravitational potential wells for less-massive dark haloes and AGN feedback, and high virial temperature of massive dark haloes. Leauthaud et al. (2012) showed that this characteristic dark halo mass varies with the redshift, which is evidence of mass downsizing at $0 < z < 1$. Behroozi et al. (2013) predicted the redshift evolution of the SHMR from $z = 8$ to $z = 0$ using numerical simulations. They concluded that star formation was most efficient at $M_h \sim 10^{12} M_\odot$ at $0 < z < 5$; however, there was a trend that the pivot halo mass became larger with increasing redshift from $z = 0$ to $z = 3$, and the conversion efficiency for the massive dark halo was the highest when $2 < z < 3$. The SHMR has been calculated based on observations at low-$z$ and $z \sim 3$; however, there have been few investigations at $z \sim 2$ because of the lack of estimates of the dark halo mass.

In this work, we describe an HOD analysis of a large number of sgzKs, exploiting high-quality ACFs to investigate the properties of dark haloes at $z \sim 2$, as well as the relationship between the sgzKs and other galaxy populations. The HOD formalism is based upon a halo model, and it enables us to calculate the dark halo mass precisely, as well as to determine the distribution of sgzKs in their host dark haloes; this enables us to connect sgzKs to their ancestors/descendants.

The aim of this paper is to discuss galaxy evolution from high-$z$ to the local Universe from the point of view of the evolution of the dark halo mass and the number of satellite galaxies. The framework of this paper is organized as follows. In Section 2, we summarize previous research, and discuss the properties of the sgzK galaxy sample and...
The very wide-field gzK galaxy survey – II

2 THE SGZK GALAXY SAMPLE AND CLUSTERING ANALYSIS

In our previous study (Ishikawa et al. 2015, hereafter referred to as paper I), we addressed difficulties in constructing a large sample of galaxies at z = 2 using both our data and publicly available data, and constructed the largest star-forming galaxy sample yet at z = 2. In this section, we briefly review our data and the clustering analysis described in paper I.

We retrieved the K-band image public archive data on the VIMOS4 region from the United Kingdom InfraRed Telescope (UKIRT) Deep Sky Survey (UKIDSS; Lawrence et al. 2007) in the Deep Extragalactic Survey (DXS). We obtained z-band photometric data for ∼3 deg² (Kashikawa et al. 2012) for the region, and retrieved Suprime-Cam z-band image data from the SMOKA data archive server (Baba et al. 2002) to extend the survey field to 5.2 deg². The z-band (λc = 8.842 μm, FWHM = 868 Å) is a custom-made filter (Shimasaku et al. 2005). We retrieved g-band images, which cover the entire field where K- and zB/z-band images were available, using the Canada–France–Hawaii Telescope Legacy Survey (CFHTLS; Gwyn 2011) archive data, rather than using B-band data. The limiting magnitudes of these K-, zB/z-, and g-band data were K = 23.31 (3σ, 2″ in AB magnitude), zB = 25.55, z = 25.36, and g = 26.08, respectively. The limiting magnitude of our K-selected catalogue was K = 23.0, which corresponds to a 70% completeness cut.

Differences in the filter set used for our gzB/zK and the original VLT-BzK filters should be considered when selecting galaxies, to ensure the same properties as in previous BzK studies. We carefully implemented band corrections for our (g − zB), (g − z), (zB − K), and (z − K) colours to convert them into VLT-(B − z) and -(z − K) colours (see Section 2.3 of paper I for further details). Following these corrections, we applied the BzK selection method (termed here the “gzK selection” method) to obtain sgzKs. The original BzK selection criterion proposed by Daddi et al. (2004) was applied, as we may consider that the colours of the objects listed in our K-selected catalogue have the same values as those colours observed using the VLT. The criterion used to select sgzKs is given by

\[(z − K) ≥ (B − z) − 0.2.\]

The number of selected sgzKs was 41,112, which represents the largest sgzK/sBzK galaxy sample yet obtained. The number counts of all K-selected galaxies and sgzKs were in good agreement with the results of previous studies.

The derived ACF amplitude exhibited a clear K-band luminosity dependence, showing that more luminous sgzKs were more strongly clustered than fainter sgzKs; this trend had been inferred by previous studies (e.g., Hayashi et al. 2007). Moreover, with our ACFs, an excess from a power law at the small angular scale was clearly seen because of the high signal-to-noise (S/N) ratio, due to the large number of samples.

Our correlation lengths showed excellent agreement with the results of almost all previous studies over all magnitude ranges. There was a tendency for bright sgzKs to exhibit stronger clustering than faint sgzKs, as was the case with the amplitude of the ACFs. We also investigated the relationship between clustering strength and the stellar mass of the sgzKs, which was consistent with previous studies (Béthermin et al. 2014; Bielby et al. 2014).

The dark halo masses were calculated by comparing the effective bias derived from the correlation length with the halo model based on Sheth et al. (2001b) and Mo & White (2002). The mean dark halo masses of sgzKs were found to be \((1.32^{+1.12}_{-1.02}) \times 10^{12} h^{-1} M_\odot, \ (2.55^{+0.42}_{-0.32}) \times 10^{12} h^{-1} M_\odot, \) and \((3.26^{+1.23}_{-1.12}) \times 10^{13} h^{-1} M_\odot\) for \(22.0 < K < 23.0,\ 21.0 < K < 22.0\) and \(18.0 < K < 21.0\), respectively. This suggests that more luminous sgzKs in the K-band reside in more massive dark haloes. We also found that the relationship between the minimum mass \(M_{\text{min}}\) and the mean mass \(\langle M_h \rangle\) of the dark halo satisfied \(\langle M_h \rangle \approx 3 M_{\text{min}}\), which is consistent with the data reported by Hayashi et al. (2007).

3 HOD ANALYSIS

3.1 The HOD Model

Some methods used to calculate the dark halo mass, such as the ACF and abundance matching, assume that one dark halo must possess only one galaxy; however, this is not always the case, especially for more massive dark haloes, which often contain satellite galaxies. Galaxy clusters, which are embedded in large massive dark haloes, have numerous member galaxies, whereas less massive dark haloes may contain no galaxy at all. Thus, a more precise halo model is required to describe the distribution of galaxies within dark haloes.

The HOD model was proposed to implement more detailed analysis by linking virialized dark haloes and the distribution of galaxies within them. The HOD framework provides a probability distribution for the number of galaxies in the dark halo as a function of the dark halo mass. In this paper, we used a standard HOD model proposed by Zheng et al. (2005), who confirmed the validity of their model by comparing observational results with a smoothed particle hydrodynamics (SPH) simulation and a semianalytic galaxy formation model. In this HOD model, galaxy occupation is clearly separated by the contribution of central galaxy, \(N_c(M)\), and satellite galaxies, \(N_s(M)\), and total galaxy occupation within dark halo, \(N(M)\), is described as

\[N(M) = N_c(M) \times \left[1 + N_s(M)\right].\]
The central galaxy occupation that satisfies the magnitude threshold is characterised by a step-like function with smoothed-cut-off as

\[ N_c(M) = \frac{1}{2} \left[ 1 + \text{erf} \left( \frac{\log M - \log M_{\text{min}}}{\sigma_{\log M}} \right) \right], \]

whereas the satellite galaxy occupation that satisfies the magnitude threshold is described by a Poisson distribution; i.e.,

\[ N_s(M) = \left( \frac{M - M_0}{M_1} \right)^\alpha. \]

We note that we set \( N_s(M) = 0 \) if the dark halo mass \( M \) satisfies \( M < M_0 \).

We have five free HOD parameters \( M_{\text{min}}, M_1, M_0, \alpha, \) and \( \sigma_{\log M} \). One of the advantages of the HOD model is that these HOD parameters have explicit physical meanings. \( M_{\text{min}} \) is an approximation of the minimum dark halo mass required to possess a central galaxy within a dark halo and \( \sigma_{\log M} \) is the cut-off parameter of central galaxy occupation. For \( N_c(M) \), \( M_0 \) is the minimum dark halo mass to form a satellite galaxy within a dark halo, \( M_1 \) is the typical dark halo mass that possesses one satellite galaxy, and \( \alpha \) is the power-law slope of the relationship between dark halo mass and the number of satellite galaxies.

The HOD framework allows for the formation of multiple galaxies within a single dark halo, which can explain the excess from a power law in the observed ACFs at the small angular scale (1-halo term), corresponding to less than the virial radius. At the large angular scale, especially at scales larger than the virial radius (2-halo term), the ACF is contributed to by galaxy pairs residing in different dark haloes; i.e., the ACF becomes the simple power law.

For the computation of ACFs in the HOD framework, we assumed the halo mass function of Sheth & Tormen (1999), halo bias of Tinker et al. (2005), and dark halo profile of an NFW profile (Navarro et al. 1997). It is noted that the HOD analysis also requires the redshift distributions of each subsample. We derived the redshift distributions, which are also required in the HOD analysis of each sgzK subsample using the COSMOS K-selected catalogue (Muzzin et al. 2013). Further details of these processes and the derived redshift distribution of each subsample are found in paper I.

### 3.2 HOD Analysis on the sgzKs

The HOD parameters can be determined by fitting the HOD 1-halo/2-halo ACFs to the observed ACFs using a least \( \chi^2 \) method; i.e.,

\[ \chi^2 = \sum_{i,j} \left[ \omega_{\text{obs}}(\theta_i) - \omega_{\text{HOD}}(\theta_i) \right] \left( C^{-1} \right)_{ij} \left[ \omega_{\text{obs}}(\theta_j) - \omega_{\text{HOD}}(\theta_j) \right] + \frac{\left[ n_{\text{obs}} - n_{\text{HOD}} \right]^2}{\sigma_{n_{\text{obs}}}^2}, \]

where \( \omega_{\text{HOD}}(\theta_i) \) and \( \omega_{\text{obs}}(\theta_i) \) are the model-predicted and the observed ACFs at a given angular scale, \( n_{\text{obs}} \) is the galaxy number density, and \( \sigma_{n_{\text{obs}}}^2 \) is the statistical 1\( \sigma \) errors of the observed number densities of sgzK galaxies, respectively. We note that the error of the galaxy number density, \( \sigma_{n_{\text{obs}}} \), is considered as both a Poisson error and cosmic variance (Trenti & Stiavelli 2008). \( (C^{-1})_{ij} \) is the \( (i,j) \) element of the inverse covariance matrix calculated by the Jackknife method (see below for more details). Galaxy number density from the HOD model is calculated by integrating the halo mass function, by weighting the number of galaxies within dark haloes (equation 2) as

\[ n_{\text{HOD}} = \int dM n(M) N(M), \]

where \( n(M) \) is the halo mass function proposed by Sheth & Tormen (1999).

It is useful to calculate the covariance matrix to estimate the correlation between other angular bins. We calculated the covariance matrix, \( C_{ij} \), of our sgzK galaxy sample using the Jackknife resampling method. We divided our survey region into \( N = 64 \) and calculated the ACF by removing one sub-region, repeating this process 64 times. The covariance matrix is calculated by

\[ C_{ij} = \frac{N-1}{N} \sum_{k=1}^{N} \left( \langle \omega_k(\theta_i) - \bar{\omega}(\theta_i) \rangle \right) \times \left( \langle \omega_k(\theta_j) - \bar{\omega}(\theta_j) \rangle \right), \]

where \( \bar{\omega}(\theta_i) \) is the average ACF of \( i \)-th angular bin. The correlation factor of Hartlap et al. (2007) is applied in the case that we convert our covariance matrix into an inverse matrix. As Coupon et al. (2012), we show the correlation coefficient of our sgzK galaxy sample, \( r_{ij} = \sqrt{C_{ij}/C_{ii}C_{jj}} \), for each luminosity subsample (Figure 1). The HOD derived ACFs of 1-halo/2-halo terms; i.e.,

\[ \omega_{\text{HOD}}(\theta_i) = \omega_{1h}(\theta_i) + \omega_{2h}(\theta_i), \]

where \( \omega_{1h}(\theta) \) and \( \omega_{2h}(\theta) \) are the ACFs of the 1-halo term and 2-halo term, respectively. We fitted \( \omega_{\text{HOD}} \) by varying the five free HOD parameters \( (M_{\text{min}}, M_1, M_0, \alpha, \sigma_{\log M}) \), using the “Population Monte Carlo (PMC)” technique (Cappé et al. 2007). The publicly available code, “CosmoPMC”, was adopted to investigate the best-fit HOD parameters in parameter space (Wraith et al. 2009; Kilbinger et al. 2010). First, we estimated best-fit HOD parameters of the overall sgzKs \((18.0 \leq K \leq 23.0)\) by varying the five parameters over a wide range. Then, differentially resampled ACFs were used to investigate the dependence of the HOD parameters on \( K\)-band luminosity. We carried out HOD analysis in two ways; (1) by varying the five HOD parameters and (2) by only varying \( M_{\text{min}}, M_1, \) and \( M_0 \) with fixed \( \alpha = 1.19 \) and \( \sigma_{\log M} = 0.254 \) corresponding to the best-fit values for the total sample.

As in Hamana et al. (2006) and Béthermin et al. (2014), we define the mean halo mass, \( \langle M_h \rangle \), and the expectation number of galaxies, \( \langle N_g \rangle \), weighted by the number of galaxies within the dark halo as follows:

\[ \langle M_h \rangle = \frac{\int_{M_{\text{min}}}^{\infty} dM Mn(M)N(M)}{\int_{M_{\text{min}}}^{\infty} dM n(M)N(M)}, \]

and

\[ \langle N_g \rangle = \frac{\int_{M_{\text{min}}}^{\infty} dM n(M)N(M)}{\int_{M_{\text{min}}}^{\infty} dM n(M)}. \]

where the low-mass cut-off of the integration was set to \( M_{\text{min}} \) to exclude the contribution of low-mass dark haloes with no galaxies.
4 RESULTS OF THE HOD ANALYSIS

4.1 Fitting Parameters

Figure 2 shows the best-fit HOD models to the observed ACFs of sgzKs. It is clear that our HOD model can describe the observed ACFs of sgzKs. The best-fit HOD parameters with 1σ error are listed in Table 1. We show the results of the best-fit HOD parameters for the case varying all HOD parameters, as well as the case with fixed α and σ_{log M}. Fixed α and σ_{log M} are derived from the HOD analysis of the total sgzK (satisfying 18.0 ⩽ K ⩽ 23.0) samples. Some studies report the best-fit values of α and σ_{log M} of various galaxy populations, although most of the HOD analysis studies used a fixed α and/or σ_{log M}.

Most studies support our fixed α and σ_{log M} (e.g., Zehavi et al. 2004; Coupon et al. 2012). Martinez-Manso et al. (2015) carried out HOD analysis on Spitzer-selected galaxies at z = 1.5 by fixing α = 1.0 and σ_{log M} = 0.2, which are consistent with our fixed α and σ_{log M}. In the local Universe, Zehavi et al. (2011) also showed α ∼ 1 and σ_{log M} ∼ 0.2 for their faint and intermediate galaxy sample (M_{r}^{max} < -20.5), although the result of their full sample, including the brightest galaxies (M_{r}^{max} < -22.0), was σ_{log M} ∼ 0.7. From here, we adopt the results of the HOD analysis in which α and σ_{log M} are fixed.

At ∼ 0.01 deg, there are systematic spikes in our ACFs, whose characteristics cannot be explained by the HOD model. The origin of this discrepancy is unclear. One possible explanation is that the halo model cannot describe the observed ACF at the scale of the virial radius. Several previous studies, especially at z ∼ 2, also showed the small excess of the observed ACF from the best-fit HOD at this scale (e.g., Wake et al. 2011; Martinez-Manso et al. 2013; McCracken et al. 2013); however, further discussion is beyond the scope of this study.

The errors of the mean halo mass, ⟨M_h⟩, and the expectation number of galaxies, ⟨N_g⟩, were estimated from the minimum/maximum values of ⟨M_h⟩ and ⟨N_g⟩ by varying the free parameter set. Figure 3 shows χ^2 confidence contour maps of the HOD parameters derived from the least χ^2 method on the M_1–M_{min} parameter planes fixing M_0, σ_{log M}, and α of those best-fit values. As shown by the data listed in Table 1 the mass quantities M_1, M_{min}, and ⟨M_h⟩ almost increased as the magnitude thresholds became brighter. This is evidence that brighter sgzKs reside in more massive dark haloes. Figure 4 shows the halo occupation functions (equation 2) of each luminosity subsample as a function of the dark halo mass. We show both halo occupation functions in the case of varying five HOD parameters (dashed lines) and fixing α and σ_{log M} (solid lines).

The expectation number of galaxies within a dark halo, ⟨N_g⟩, was similar between each subsample. It follows that the ratio of the number of K-faint sgzKs in less-massive dark haloes to the number of K-bright sgzKs in massive dark haloes was close to unity. Nevertheless, we should keep in mind that ⟨N_g⟩ is strongly affected by α, which represents the satellite galaxy formation efficiency in dark haloes, and which was fixed in this analysis. A possible dependence of the galaxy limiting magnitude on α should be investigated using a larger galaxy sample as part of a future extensive survey, such as the Hyper Suprime-Cam (HSC) survey.

4.2 Dark Halo Mass of sgzK Galaxies

In paper I, we determined the dark halo mass corresponding to sgzKs using large-scale galaxy clustering (Mo & White 1996), which assumes a one-to-one correspondence. HOD analysis enables us to derive a more accurate dark halo mass based on a more realistic HOD halo model.

Figure 5 shows a comparison of the dark halo masses calculated using the HOD analysis and the ACFs. The dark halo masses calculated using the HOD analysis were several times larger than those calculated using the ACFs. We note that the definitions of the mean halo masses with these two methods differ slightly. The mean halo mass from the HOD analysis is weighted by the number of galaxies in a dark halo, which tends to make ⟨M_h⟩ larger than the estimate from the ACF; that is because HOD formalism does not assume a one-to-one correspondence, as also mentioned in Geach et al. (2012).

We also compared our sgzK dark halo masses with those of the previous studies, as shown in Figure 5. Geach et al. (2012) investigated the mass of Hα emitters (HAEs) at z = 2.23, and Béthermin et al. (2014) estimated the mass of sBzKs at z ∼ 2 in the COSMOS field. Our results are in good agreement with these data. Béthermin et al. (2014) reported little difference between data obtained using the two methods. However, this may be caused by large error bars in their HOD analysis.

5 DISCUSSION

5.1 The Luminosity Dependence of the HOD Parameters

As we showed in Section 4.1, the HOD parameters exhibit a dependence on the K-band luminosity, which has been reported previously (e.g., Zehavi et al. 2011).
central galaxy (the low-mass halo is proportional to the luminosity of the $L_{\text{red}}$ galaxies at $z_{\text{a}}$). Ishikawa et al. (2009), using the same HOD model with varying resampling method.

Figure 1. Correlation coefficient of the sgzK galaxy sample. Left, middle, and right panels show the correlation coefficient results of $18.0 < K < 21.0$, $21.0 < K < 22.0$, and $22.0 < K < 23.0$ subsamples, respectively. These results were derived using the Jackknife resampling method.

$^a$ The number of the brightest sgzK was too small to put constraints on the $1\sigma$ limit for $M_0$.

Martinez-Manso et al. (2015). This is caused by the fact that more-luminous galaxies generally reside in more-massive dark haloes.

Figure 2 shows the relationship between the threshold absolute K-band magnitudes of the sgzKs and the HOD parameters $M_1$ and $M_{\text{min}}$. Zehavi et al. (2005) showed that the halo mass of galaxies with luminosity $L < L_*$ was weakly dependent on the luminosity of the galaxy, whereas the halo mass of galaxies with a luminosity $L > L_*$ increased sharply with increasing luminosity. This is because a large fraction of baryons within a massive dark halo tends to form satellite galaxies that are below the luminosity threshold, and then accrete to the central galaxy. Zehavi et al. (2011) also found that the clustering amplitude of galaxies with luminosity $L < L_*$ increased slowly, whereas the clustering amplitude increased sharply for $L \gtrsim L_*$, showing that $M_1$ and $M_{\text{min}}$ had a similar dependence on the luminosity. Moreover, Zheng et al. (2004), using the same HOD model with varying $\alpha$ and $\sigma_{\log M}$, reported a similar relation for luminous red galaxies at $z \sim 0.3$, showing that the dark halo mass of the low-mass halo is proportional to the luminosity of the central galaxy ($L \propto M_h$), whereas high-mass dark haloes followed the relation $L \propto M_h^{0.5}$.

As shown in Figure 2, our data show different slopes for the bright sgzKs and faint sgzKs, although the slope of the power law was somewhat uncertain because we have only three data points, which makes it impossible to determine the turning magnitude; this trend is also seen in the local Universe (e.g., Zheng et al. 2009, Zehavi et al. 2011). Our results for high-mass sgzKs exhibit a similar behaviour to the high-mass low-$z$ galaxies (Zehavi et al. 2005, 2011, Zheng et al. 2004), indicating that baryons are less likely to accrete into the central galaxies at $z \sim 2$, which is also seen for low-$z$ galaxies. Zheng et al. (2009) inferred that baryons are likely to be consumed to form faint satellite galaxies rather than accrete into bright central galaxies. Our result of a massive dark halo indicates that the trend may be true, even in the $z \sim 2$ Universe.

$M_{\text{min}}$, representing the threshold dark halo mass of the central galaxy formation, are larger at $z \sim 2$ than $z = 0$. This suggests that galaxies at higher-$z$ can be formed only in very massive dark haloes, whereas less-massive dark haloes can form galaxies at lower-$z$, which is known as downsizing (e.g., Fontanot et al. 2009). On the other hand, $M_1$, which represents the threshold dark halo mass of the satellite galaxy formation, are also larger at $z \sim 2$ than $z = 0$. Our result implies that satellite galaxies are less likely to be formed in the high-$z$ Universe than
in the local Universe; also, the HOD mass parameters show the same luminosity dependence as that for the local Universe. It should be noted that the galaxy populations of this work and Zehavi et al. (2011) are not completely identical; Zehavi et al. (2011) used volume-limited SDSS galaxy samples \((z \leq 0.2)\), whereas our sample is confined to the star-forming galaxy at \(z \sim 2\).

5.2 The Evolution of sgzKs by Tracing the Halo Mass Evolution

The mass assembly history can be traced from the mass evolution of dark haloes because the halo mass increases monotonically as a function of cosmic time due to merging.

The halo mass evolution can be evaluated from the extended Press–Schechter model (EPS model; Press & Schechter 1974, Bond et al. 1991, Bower 1991), which describes the number density of objects in the Universe by modelling the halo merger, which is essential for the ΛCDM structure formation. A more detailed description of the EPS model can be found in Hamana et al. (2006, and the references therein).

First, we trace the dark halo mass evolution of LBGs at \(z \sim 4\) derived by Hamana et al. (2006) to investigate the relationship between sgzKs and the higher-\(z\) galaxy population. Figure 7 shows a comparison of the expected dark halo masses between LBGs and sgzKs. It should be noted that the halo occupation models that are adopted by
this work and Hamana et al. (2006) are different. The HOD model of Hamana et al. (2006) is a simple power-law occupation that does not distinguish the central galaxy occupation from the satellite galaxy occupation. All assumptions (e.g., cosmological parameters and halo mass function) of Hamana et al. (2006), except for $\sigma_8$ that was assumed to be $\sigma_8 = 0.9$ in Hamana et al. (2006), are the same as those we adopted. LBG samples of Hamana et al. (2006) were taken from the Subaru/XMM-Newton Deep Survey (Ouchi et al. 2005). The mass evolutions of LBGs from $z = 4$ to $z \sim 2$ are shown in Figure 7, where the hatched regions represent the 68% confidence intervals of the redshift evolution of the mean dark halo masses of LBGs. The dark halo mass of our bright sgzKs ($21.0 < K \leq 22.0$) was equivalent to the evolved dark halo mass of bright LBGs ($i' < 26.0$) at $3 < z < 4$, whereas the dark halo mass of our faint sgzKs ($22.0 < K \leq 23.0$) was equivalent to the mass of the evolved dark halo mass of faint LBGs ($i' < 27.0$), although there was a slight difference between the mass of the bright sgzKs and the faint sgzKs. This result may be expected, because galaxies with a higher SFR at larger redshifts produce a considerably greater number of stars and evolve into galaxies with larger stellar mass at smaller redshifts. However, we should consider that these two galaxy populations were selected using different selection criteria. It should be noted that the dark halo masses of sgzKs with magnitude $21.0 < K \leq 22.0$ and $22.0 < K \leq 23.0$ satisfy the evolved dark halo masses of both bright and faint LBGs within the range of $1\sigma$ confidence intervals, calculated using the EPS formalism. Thus, we cannot clearly determine which LBG is an ancestor of the bright/faint sgzKs; however, the probability distribution functions (PDFs) of mass assembly of LBGs show that the descendants of bright (faint) LBGs at $z \sim 4$ are likely to be bright (faint) sgzKs (see right panel of Figure 7). It is necessary to consider the evolutionary link of baryonic properties (e.g., stellar mass and galaxy age), in addition to the evolution of dark halo mass, to validate the evolutionary history of galaxies.

Figure 7 shows that there is a trend whereby the mean halo mass was smaller for LBGs and sgzKs with fainter limiting magnitudes. This is caused by different physical mechanisms for each galaxy population. For LBGs, the detection band was the $i'$-band, which corresponds to $\sim 1500\text{\AA}$ in the rest frame. LBGs are known to be actively star-forming, and the UV radiation is mainly emitted by young, massive stars; i.e., more-luminous LBGs at UV wavelengths have
within a dark halo, M_{\text{halo}}

typical early-type galaxies. Intermediate luminosity sgzKs
increased up to 200 M_{\odot} yr^{-1} and exhibited a plateau for higher SFRs; however, such flattening of the SFR–halo mass relation is significant only at 1.7\sigma; and this should be confirmed via a more precise analysis in the future.

We note that sgzKs were selected according to the K-band luminosity, which is contributed to mainly by old, less-massive stars, and corresponds to the stellar mass directly. A strong correlation has been reported between the K-band luminosity of sBzKs and the stellar mass (e.g., Lin et al. 2012; Béthermin et al. 2014). However, the correlation between the dark halo mass of sBzKs and sBzKs and the SFRs remains unclear. Béthermin et al. (2014) argued that the dark halo mass of sBzKs increased up to 200 < SFR < 0.8; therefore, such flattening of the SFR–halo mass relation is significant only at 1.7\sigma; and this should be confirmed via a more precise analysis in the future.

The expected number of LBGs in a dark halo reported by Hamana et al. (2004) was (N_{\emptyset}) \sim 0.4; however, we find the expected number of sgzK to be (N_{\emptyset}) \sim 0.8. This discrepancy may result from differences in the selection criteria. The number of satellite galaxies selected by stellar mass at lower-z was more than that selected by SFR at higher-z. In addition, it was not possible to identify the ancestors of the brightest sgzKs at z \sim 4. This is because the counterparts of the brightest sgzKs at z \sim 4 are thought to be brighter LBGs than those LBGs satisfying i' < 26.0; therefore, those bright LBGs are rare objects in the distant Universe. Further extensive surveys in the future, i.e., HSC survey, are expected to reveal a sufficient number of bright LBG candidates to determine the dark halo mass more accurately.

We traced the expected evolutionary history of our sgzKs to the local Universe. Figure 7 shows the mass evolutions of sgzKs from z \sim 2 to z \sim 0 (shown by the hatched regions). The mean dark halo masses of local galaxies with various luminosities were calculated by Zehavi et al. (2011), and these data were applied to the HOD analysis of local galaxies (z \lesssim 0.2) from the SDSS DR7 to investigate the dependence of the clustering strength on the physical properties of galaxies (e.g., luminosity and colour).

From the dark halo mass evolution estimated by the EPS formalism, the faintest sgzKs (22.0 < K \lesssim 23.0) at z \sim 2 \langle M_{\text{halo}} \rangle \sim 4 \times 10^{12} h^{-1} M_{\odot} \rangle evolve to (M_{\text{halo}}) \sim (7 - 20) \times 10^{12} h^{-1} M_{\odot}, which corresponds to the dark halo mass of the local late-type galaxies, such as the Milky-Way, or typical early-type galaxies. Intermediate luminosity sgzKs (21.0 < K \lesssim 22.0) at z \sim 2 with a mass of \langle M_{\text{halo}} \rangle \sim 7 \times 10^{12} h^{-1} M_{\odot} \rangle evolve to \langle M_{\text{halo}} \rangle \gtrsim 10^{13} h^{-1} M_{\odot}, which corresponds to the dark halo mass of massive elliptical galaxies or galaxy groups in the local Universe. The dark halo mass of the brightest sgzKs (18.0 \lesssim K \lesssim 21.0) at z \sim 2, with a mass of \langle M_{\text{halo}} \rangle \sim 1 \times 10^{14} h^{-1} M_{\odot} \rangle, evolve to \langle M_{\text{halo}} \rangle \sim (2 - 4) \times 10^{14} h^{-1} M_{\odot}, which corresponds to the dark halo mass of the most massive systems in the local Universe, such as rich clusters of galaxies.
Béthermin et al. (2014) investigated galaxy evolution by tracing the dark halo mass from $z \sim 2$ to $z \sim 0$ using the halo growth model reported by Fakhouri & Ma (2010). They inferred that sBzKs with a mass of $\langle M_h \rangle \sim 3 \times 10^{11} M_\odot$ grew to the most massive field galaxies with a mass of $\langle M_h \rangle \sim 3 \times 10^{12} M_\odot$, a halo with a mass of $\langle M_h \rangle \sim 3 \times 10^{13} M_\odot$ grew to form galaxy groups, and sBzKs/pBzKs with a mass of $\langle M_h \rangle \sim 3 \times 10^{13} M_\odot$ evolved into galaxy clusters in the local Universe. This differs slightly from our analysis; we find that the halo mass evolution was approximately $0.5$ dex from $z \sim 2$ to $z \sim 0$, whereas the halo mass evolution reported by Béthermin et al. (2014) was approximately one order of magnitude higher. This difference in the halo growth rate led to differences in the corresponding progenitors of the $z \sim 2$ galaxies.

In summary, our results suggest that faint LBGs at $z \sim 4$ could evolve into faint sgzKs ($22.0 < K < 23.0$) at $z \sim 2$ and to the Milky-Way-like galaxies or elliptical galaxies in the local Universe, whereas bright LBGs at $z \sim 4$ could evolve into intermediate luminosity sgzKs ($21.0 < K < 22.0$) and into the most-massive elliptical galaxies or central galaxies of the galaxy groups in the local Universe, and the most-luminous sgzKs ($18.0 \leq K \leq 21.0$) could evolve into the most massive systems in the local Universe; i.e., the central galaxies of the galaxy clusters. However, these evolutionary scenarios were determined by only considering the evolution of the dark halo mass. It may not be straightforward to relate different galaxy populations at different redshifts, as they may follow different star-formation histories, which are traced by other physical properties such as SFR, stellar mass, and age. In the following section, we discuss the evolution of galaxy populations, which provides another point of view from which to analyse our galaxy evolution model.

5.3 Galaxy Evolution by Tracing the Number of Satellite Galaxies

One advantage of the HOD formalism is that it enables us to describe the number of galaxies in a dark halo for a given dark halo mass. Because of this characteristic of the HOD formalism, we were able to trace the number evolution of satellite galaxies within a dark halo, which is not possible if we assume one-to-one galaxy–halo correspondence. In this section, we discuss the number evolution of satellite galaxies in a dark halo using our sgzKs, assuming that galaxies evolve so as to follow the dark matter halo evolution predicted using the EPS (see Sec. 5.1).

First, we consider the evolution of dark halo with $M'_f$; this defines the mass of the dark halo occupied by only one galaxy at $z \sim 2$, satisfying $N(M'_f) = 1$ for each luminosity subsample, to investigate the number evolution of the satellite galaxy within the dark halo. We follow the evolution of the dark halo with mass of $M'_f$ based on the EPS formalism from $z \sim 2$ to $z = 0$; the dark halo mass at $z = 0$ was determined as the mass in which the PDF of the dark halo mass evolution reaches a peak; its error is in the range of $1\sigma$ confidence interval of the PDF. The number of the satellite galaxies in the dark halo at $z = 0$ was calculated by the halo occupation function (equation 2) at an evolved dark halo mass, with the best-fit HOD parameters of Zehavi et al. (2011). We note that we took into account both errors of the evolved dark halo mass and HOD parameters of Zehavi et al. (2011) to evaluate the number of satellite galaxies.

Figure 7 shows the expected number of satellite galaxies at $z \sim 0$ for a dark halo, which corresponds to a central galaxy with no satellite galaxies at $z \sim 2$. In this figure, the horizontal axis represents the absolute rest $r$-band magnitudes, which corresponds to the $K$-band limiting magnitude of the sgzKs at $z \sim 2$, and the vertical axis is the number of satellite galaxies that are expected to be formed in the dark haloes at $z = 0$. The colour difference indicates a different absolute magnitude of satellite galaxies at $z = 0$. More-luminous galaxies tend to have more satellite galaxies at $z = 0$, and a large fraction of these satellite galaxies are faint. In dark haloes that contain the faintest central sgzKs with $M'_f \geq 19$ at $z \sim 2$, approximately three satellite galaxies with luminosity equal to that of central sgzKs at $z \sim 2$ are expected to form. However, brighter satellite galaxies are unlikely to form in the dark haloes of these faint sgzKs. In other words, dark haloes with the faintest sgK evolve into dark haloes that contain $\leq 10$ faint galaxies and no bright galaxies at $z = 0$. In the dark haloes that contained the brightest central sgzKs $M'_1 \geq 22$ at $z \sim 2$, approximately 100 satellite galaxies are expected to be formed by $z = 0$. This is consistent with the results described in Section 5.2; i.e., local galaxy groups/clusters that contain 100 or more member galaxies. Few of the brightest satellite galaxies had similar luminosity to those of sgzKs; i.e., sgzKs that reside in haloes at $z \sim 2$ would become a central galaxy of a galaxy cluster in the local Universe, especially the brightest cluster galaxies (BCGs).

Based on the discussion of the number evolution of satellite galaxies, the faintest sgzKs appear to evolve into the
Milky-Way-like galaxies whereas the brightest sgzKs evolve into the central galaxies of galaxy clusters in the local Universe, especially BCGs. These results are consistent with the implications of the discussion of galaxy evolution from considerations of the evolution of the dark halo mass.

5.4 Stellar-to-Halo Mass Ratio

Figure 8 shows a comparison between the results of our SHMRs, the theoretical prediction of Behroozi et al. (2013), and the observed SHMRs reported by Foucaud et al. (2010), Geach et al. (2012) and McCracken et al. (2013). The stellar mass was determined from the K-band magnitudes and (z−K) colours of each of the sgK galaxies (Kodama et al. 2004; Kovama et al. 2013, see paper I for more details), and ($M_\text{h}$) was used as the dark halo masses. It should be noted that the SHMR, in principle, should be calculated by the ratio between the dark halo mass and all stellar components within the dark halo (e.g., Kravtsov et al. 2014); however, Behroozi et al. (2013) calculated the SHMRs via an abundance matching method. Our data, as well as those of Geach et al. (2012) and McCracken et al. (2013), were calculated using an HOD analysis. Our data points are almost in good agreement with the theoretical model, as well as the other observations. The SHMRs of our sgzKs exhibit almost identical values at $z \sim 0$ within the $1\sigma$ confidence level, consistent with the theoretical predictions for SHMRs with $M_\text{h} \gtrsim 10^{12} h^{-1} M_\odot$, and do not significantly change between $z \sim 0$ and $z \sim 2$.

Our results are almost consistent with the prediction of the model reported by Behroozi et al. (2013); however, there was a slight difference in the trend, especially for the SHMR of the least massive haloes; the SHMR calculated from our data was smaller than the prediction of the model at $z \sim 0$ as well as at $z \sim 2$. This discrepancy may be due to differences in the galaxy populations. Our data were based on sgzKs, whereas Behroozi et al. (2013) did not take into account galaxy types when assigning galaxies to dark haloes via abundance matching. Tinker et al. (2013) also investigated this relationship over the redshift range of $0.22 < z < 1.00$, distinguishing the differences in galaxy populations as star-forming galaxy samples, passive galaxy samples, and all galaxy samples. They inferred that, especially for galaxies with a halo mass of $M_\text{h} \gtrsim 10^{12} M_\odot$, the stellar mass of a central galaxy depends on the population of the galaxy samples with a fixed dark halo mass due to differences in the growth rates of galaxies. With our samples, however, we consider only star-forming galaxies, whereby the central galaxy has a smaller stellar mass than the other two galaxy populations (Tinker et al. 2013). This may lead to a smaller SHMR at $M_\text{h} \sim 3 \times 10^{12} h^{-1} M_\odot$ than that reported by Behroozi et al. (2013). The smaller SHMR of our data compared with that of McCracken et al. (2013) that sampled all galaxies, including passive galaxies, may also be attributed to differences in the galaxy populations. The HAEs (Geach et al. 2012), which are in the early phase of star-forming activity, also show significantly lower SHMR than other galaxies.

6 CONCLUSIONS

We have described the results of HOD analysis of star-forming galaxies at $z \sim 2$. Our high-quality ACFs were based on a large sgzK galaxy sample and are sufficiently accurate to allow the use of HOD analysis to determine accurate dark halo masses.
The major conclusions of this work may be summarized as follows.

(i) The ACFs of sgzKs were well described by the halo model based on the HOD formalism, and we were able to estimate accurate dark halo masses and HOD parameters. The resulting HOD parameters enabled us to determine the dark halo mass, \( \langle M_h \rangle \), and the expectation number for dark haloes. The mean dark halo masses of our sgzK galaxies were \((4.55_{-0.60}^{+0.42}) \times 10^{12} h^{-1} M_\odot\), \((6.91_{-1.05}^{+0.77}) \times 10^{12} h^{-1} M_\odot\), and \((6.12_{-1.37}^{+1.32}) \times 10^{13} h^{-1} M_\odot\) for \(22.0 < K < 23.0\), \(21.0 < K < 22.0\) and \(18.0 < K < 21.0\), respectively. The HOD mass parameters, \(M_1\), \(M_{\text{min}}\), \(M_0\), and \(\langle M_h \rangle\), almost all increased monotonically as a function of the magnitude threshold, which suggests that more-luminous galaxies reside in more-massive dark haloes. The expectation numbers for sgzKs in a dark halo were nearly consistent within the different luminosity bins. This implies that the expectation number of faint sgzKs residing in less-massive dark haloes and bright sgzKs residing in more-massive haloes was almost identical. The HOD-based mean dark halo masses were several times larger than the mean halo masses determined by large-scale galaxy clustering. This discrepancy may be due to differences in the definition of the mean halo mass, which was also suggested by Geach et al. (2012).

(ii) We find that \(M_1\) and \(M_{\text{min}}\) for faint sgzKs are approximately proportional to the luminosity, whereas bright sgzKs follow \(L \propto M_0^{1.9}\), as is the case for galaxies in the local Universe. This is because baryons in massive dark haloes tend to form faint satellite galaxies, which are below the luminosity threshold, rather than accrete central galaxies; this confirms the same trend at \(z \sim 2\). Our \(M_{\text{min}}\) was larger than in the local Universe (Zehavi et al. 2013) over all magnitudes, implying that galaxies are formed only in massive dark haloes at \(z \sim 2\), and that less-massive dark haloes form galaxies more slowly, known as downsizing. Additionally, \(M_1\) was also larger than that of Zehavi et al. (2011), suggesting that satellite galaxies are less likely to be formed at \(z \sim 2\) than in the local Universe.

(iii) We investigated the relationship between sgzKs and galaxy populations at low- and high-redshifts by tracing the dark halo mass using the EPS formalism. Faint LBGs (\(i' < 27.0\)) at \(z \sim 4\) are expected to evolve into faint sgzKs (\(22.0 < K < 23.0\)), whereas bright LBGs (\(i' < 26.0\)) are expected to evolve into intermediate luminosity sgzKs (\(21.0 < K < 22.0\)). The brightest sgzKs at \(z \sim 2\) appear to have evolved from more luminous LBGs, the dark halo mass of which is difficult to calculate due to the small number density. We expect to be able to obtain further luminous LBG candidates for the ancestors of our brightest sgzKs in future wide-field observation. We also considered the evolution of the halo mass of our sgzKs to the local Universe and compared this with the results of Zehavi et al. (2011). Our analysis suggested that faint sgzKs could evolve into Milky-Way-like galaxies or elliptical galaxies, intermediate luminosity sgzKs could evolve into massive elliptical galaxies or the central galaxies of galaxy groups, and that the brightest sgzKs could evolve into the central galaxies of galaxy clusters; i.e., BCGs in the local Universe.

(iv) We also investigated the number evolution of satellite galaxies in a dark halo using HOD analysis. In a dark halo that contains one faint sgzK at \(z \sim 2\), \(\lesssim 10\) faint satellite galaxies with similar luminosity to the central sgzK were formed at \(z = 0\). However, a dark halo that contained only one of the brightest sgzKs evolves into a massive system that contains more than 100 galaxies in the local Universe, which corresponds to galaxy clusters. This is consistent with the results of galaxy evolution based on the evolution of the dark halo mass.

(v) We calculated the SHMRs from our sgzKs, and compared these with predictions using the model reported by Behroozi et al. (2013). Our results were in good agreement with the results of the model; i.e., the SHMR at \(z \sim 2\) did not change significantly compared with the equivalent relation at \(z \sim 0\); however, our SHMR for the faintest bin was slightly smaller than that reported by Behroozi et al. (2013) and McCracken et al. (2015). One possible explanation for this discrepancy is the difference in galaxy populations.

ACKNOWLEDGMENTS

We thank the referee for his/her useful comments to improve this paper. This work is based on data collected at the Subaru Telescope, which is operated by the National Astronomical Observatory of Japan (NAOJ). This research was supported by the Japan Society for the Promotion of Science through Grant-in-Aid for Scientific Research 23340050 and 15H03645.
