Abstract

TiO$_2$ is a promising environment friendly, low cost, and high electrochemical performance material. However, impediments like high internal ion resistance and low electrical conductivity restrict its applications as electrode for supercapacitor. In the present work, atomic layer deposition was used to fabricate TiO$_2$ nanomembranes (NMs) with accurately controlled thicknesses. The TiO$_2$ NMs were then used as electrodes for high-performance pseudocapacitors. Experimental results demonstrated that the TiO$_2$ NM with 100 ALD cycles had the highest capacitance of 2332 F/g at 1 A/g with energy density of 81 Wh/kg. The enhanced performance was ascribed to the large surface area and the interconnectivity in the case of ultra-thin and flexible NMs. Increased ALD cycles led to stiffer NMs and decreased capacitance. Moreover, one series of two supercapacitors can light up one light-emitting diode with a working voltage of ~ 1.5 V, sufficiently describing its application values.

Keywords: Atomic layer deposition, TiO$_2$ nanomembranes, Electrode, Supercapacitor

Introduction

With the maturation of energy storage technology [1], supercapacitors have received vast attention due to their high power density, fast charge-discharge rate, and good cycling performance [2–4]. Pseudocapacitor is an important class of supercapacitors, which can deliver attractive high capacitance and energy density compared with electrochemical supercapacitors [5–7]. In the past few decades, the transition metal oxides (e.g., RuO$_2$ [8], MoO$_2$ [9], MnO$_2$ [10], Ni/NiO [11], Co$_3$O$_4$ [12], and TiO$_2$ [13]) and hydroxides [14–16] were used as classic electrode materials for pseudocapacitors owing to low cost, low toxicity, multiple oxidation states [17], and great flexibility in structures and morphology. However, their thermal instability, impurity defects, and rate capability are usually limited by the inadequate conductivity to support fast electron transport required by high rates. In order to solve these problems, low-dimensional TiO$_2$ structures (1D, 2D, 2D + 1D, and 3D) with high surface-to-volume ratio, good surface structure, great electrical and thermal stability, favorable energy band gap properties, and high dielectric constant have been engaged as promising electrode materials for supercapacitors [18–22]. Especially, we think that 2D nanomembrane (NM) structures with excellent flexibility should have great potential in electrode applications. The thickness control of nanomembrane is therefore crucial in fabricating functional devices in well-defined nanoworld [23]. In addition, large-scale manufacturing of nanoscale materials is also crucial for practical applications [24]. One may note that atomic layer deposition (ALD) is a captivating technique used to construct nanodevices [25, 26]. This powerful technique can deposit thin films layer by layer with accurate thickness control and can conformally cover 3D structures with high aspect ratio [27–30], and the productivity can thus be greatly enhanced. In the current work, we present the fabrication of 2D TiO$_2$ NMs with different thicknesses by performing ALD on 3D porous polymer template with large surface area [31, 32]. Microstructural characterization elucidates that the crystal structure of NM is a mixture of anatase and rutile phases. Electrochemical characterizations demonstrate that the ultra-thin and flexible...
NM s have the enhanced performance due to the large surface area and the interconnectivity among the NMs. The improved ion transportation causes Faradaic reaction on the surface as well as in the bulk [33], resulting in increased capacitance and energy densities.

Methods

Fabrication of TiO$_2$ NMs

TiO$_2$ NMs with various thicknesses (100, 200, and 400 ALD cycles) were deposited on a commercially available polyurethane sponge by using ALD technique. Tetra-kis dimethylamide titanium (TDMAT) and de-ionized (DI) water were used as precursors in the presence of nitrogen (N$_2$) gas which served as both carrier and purge gases. The flow rate of the carrier gas was 20 sccm. A typical ALD sequence includes TDMAT pulse (200 ms), N$_2$ purge (20,000 ms), H$_2$O pulse (20 ms), and N$_2$ purge (30,000 ms). The precursors used were purchased from J&K Scientific Ltd., China. The precursor conformally covered the three-dimensionally porous sponge, which led to promoted productivity due to the large surface area of the template [34]. The TiO$_2$-coated sponges were calcinated at 500 °C for 4 h in an O$_2$ flow of 400 mL/min, and the template was completely removed. The resultant TiO$_2$ NMs were crushed and cleaned in ethanol, hydrochloric acid (HCl), and DI water.

Preparation of Electrode

In order to fabricate high-performance supercapacitor, TiO$_2$ NMs with 100, 200, and 400 ALD cycles were used as the active material and polytetrafluoroethylene (PTFE) was used as binder. The contents of TiO$_2$ NMs and binder were 90 wt% and 10 wt%, respectively. A homogeneous TiO$_2$ NMs slurry was obtained by mixing the NMs and binder with a small quantity of ethanol, and a milling process was engaged. The prepared uniform slurry was deposited onto the cleaned nickel foam and then the sample was degassed at 60 °C for 2 h in vacuum. In order to complete the electrode fabrication, the sample was pressed under 10 MPa pressure. The prepared TiO$_2$ NMs electrode was soaked in 1 M KOH solution for 12 h to activate the electrode. The loading densities of active materials were about ~ 1.5 mg cm$^{-2}$ for all electrodes. The mass of the TiO$_2$ NMs on nickel foam was obtained by calculating the mass difference between the electrode and nickel foam [35].

Microstructural Characterization

The crystallographic structure of the TiO$_2$ NMs was inspected by X-ray diffraction technique (XRD). The XRD patterns were recorded by using a Bruker D8A Advanced XRD with Cu Kα radiation ($\lambda = 1.5405$ Å). The morphology of TiO$_2$ NMs was examined by scanning electron microscopy (SEM, Zeiss Sigma). The Raman spectra of the samples were carried out on a Horiba Scientific Raman spectrometer ($\lambda = 514$ nm). The elemental analysis and chemical state of the TiO$_2$ NMs were obtained by using a PHI 5000C ECA X-ray photoelectron spectroscopy (XPS), with C 1s peak at 284.6 eV as the standard signal. Atomic force microscopy (AFM, Dimension Edge, Bruker, USA) with tapping mode was used for surface topography of TiO$_2$ NMs.

Electrochemical Characterization

Three-electrode system was utilized to study the electrochemical properties of the TiO$_2$ NMs working electrode where Ag/AgCl and platinum foil were acted as a reference electrode and counter electrode, respectively. The cyclic voltammetry (CV), chronopotentiometry (CP), and electrochemical impedance spectroscopy (EIS) measurements were accomplished on a Chenhua CHI 660E electrochemical workstation at 25 °C in 1 M KOH aqueous solution. EIS results were obtained over the frequency range of 100 KHz to 1 Hz with an amplitude of 5 mV. The calculation methods of specific capacitances and energy/power densities are described in Additional file 1.

Results and Discussion

The preparation of TiO$_2$ NMs is shown in Fig. 1a. The TDMAT and H$_2$O were used as ALD precursors to deposit TiO$_2$ on polyurethane sponge template. The reaction total can be written as: [36]

\[
\text{Ti}(\text{N(CH$_3$)$_2$})_4 + \text{TiO}_2 + \text{OH}^- \rightarrow \text{NH(CH$_3$)$_2$} + \text{TiO}_2 + \text{OH}^- + 3\text{NH}_2\text{CH}_3
\]

(1)

The total reaction can be written as:

\[
\text{Ti}(\text{N(C$_2$H$_6$)$_2$})_4 + 2\text{H}_2\text{O} \rightarrow \text{TiO}_2 + \text{TiO}_2 + \text{OH}^- + 3\text{NH}_2\text{CH}_3
\]

(2)

The sponge with TiO$_2$ NM coated was then heated to high temperature. During calcination at 500 °C under oxygen atmosphere, the polymer template was converted into CO$_2$ and left the 3D porous NM structure behind [34]. Crushing this 3D porous structure led to the fabrication of powder-like structure in white (Fig. 1a). The morphologies of TiO$_2$ NMs with 100, 200, and 400 ALD cycles were further observed by SEM and are demonstrated in Fig. 1b–d. We found the lateral sizes of the NMs with different ALD cycles are typically around tens of microns. The thickness of TiO$_2$ NMs fabricated in this work was probed by AFM technique and the results are presented in Additional file 1: Figure S1. The average
thickness of TiO₂ NMs with 100, 200, and 400 ALD cycles are ~15, 34, and 71 nm, respectively. With the increase of ALD cycles, TiO₂ NMs is converted into a thicker and stiffer sheet. The corresponding insets in Fig. 1b–d demonstrate that the thickness of NMs is uniform, and some small creases represent the flexibility of TiO₂ NM especially in the thinner cases. The NMs deposited by ALD can replicate the morphology of the original substrate (i.e., sponge) and therefore some irregular surface structures in the insets of Fig. 1c and d may originate from the template or from the calcination process [37]. Normally, TiO₂ has three different crystal structures: anatase (tetragonal; space group, I₄₁/amd), brookite (orthorhombic; space group, Pcab), and rutile (tetragonal; space group, P4₂/mnm) phases. Here, we carried out detailed characterization to investigate the microstructural properties of TiO₂ NMs. The crystal structures of the TiO₂ NMs were investigated by XRD, and the corresponding results are shown in Fig. 2a. The diffraction peaks are indexed to TiO₂ with anatase and rutile structures (see Additional file 1: Figure S2), indicating the existence of the mixture phase in TiO₂ NMs calcinated at 500°C. The co-existence of both phases could be valuable for supercapacitor performance of TiO₂ NMs [30, 38]. Figure 2b further demonstrates the Raman spectra of corresponding TiO₂ NMs, which can also be used to identify the phases existed in the NMs. Here, five Raman peaks ascribed to anatase TiO₂ are located at ~142 (E₉), 393 (B₁g), 397 (B₁g), 513 (A₁g), 515 (A₁g), and 634 (E₉) cm⁻¹ [39], and they can be observed in all three samples. On the other hand, the 445 cm⁻¹ (E₉) peak is connected with rutile phase and can be seen in all three samples but the Raman peak at 610 cm⁻¹ (A₁g) appears only in TiO₂ NM with 400 ALD cycles [40]. The emergence of 610 cm⁻¹ (A₁g) peak reflects the microstructural change, which might be caused by the insufficient oxygen for the thick NM during heat treatment in oxygen [41]. This indicates that the increased number of ALD cycles has a remarkable influence on the crystal structure of the TiO₂ NMs, which can be probed by XRD and Raman spectra shown in Fig. 2. The electronic configuration of the TiO₂ NMs was also studied by XPS and the results are displayed in Additional file 1: Figure S3. The results prove the existence of Ti⁴⁺ in all NMs and a small shift of the peaks may be ascribed to the change in crystal structure as mentioned above. In order to study the electrochemical performance of the TiO₂ NMs, three-electrode electrochemical system including a reference electrode, counter electrode, and a working electrode was operated. Here, Ag/AgCl was
served as a reference electrode to control the potential difference and Pt counter electrode was engaged as an electron source to transit current towards TiO$_2$ NMs working electrode in the presence of aqueous electrolyte (1 M KOH solution). It is worth noting that the functional voltage of supercapacitor depends on the electrolyte, and aqueous electrolyte with well electronic conductivity and high dielectric constant may be helpful in attaining higher capacitance [42]. The acquired CV and CP curves of electrodes made from TiO$_2$ NMs with 100, 200, and 400 ALD cycles are displayed in Fig. 3a, b and Additional file 1: Figure S4. One can see that in Fig. 3a, all CV curves of three electrodes made from TiO$_2$ NMs with different thicknesses exhibit redox peaks. The CV curve of pure nickel foam is also plotted for comparison, and no obvious peak can be observed. Generally, the appearance of redox peaks can be associated to cation interactions on the surface of the TiO$_2$ NMs, and the interaction can be expressed as: [43]

$$(\text{TiO}_2)_{\text{surface}} + \text{M}^+ + e^{-} \leftrightarrow (\text{TiO}_2 - \text{M}^+)_{\text{surface}}$$

where M$^+$ could be H$_3$O$^+$ or K$^+$ in the electrolyte. The change between different oxidation states of Ti ion suggests its potential as redox electrode material. In response of fast surface Farad reaction, the CV curves of TiO$_2$ NMs exhibit larger areas compared with that of pure Ni-foam, implying the higher specific capacitance value of TiO$_2$ NMs. Specifically, one can see the area of the CV curves decreases with the ALD cycles, suggesting a decrease of capacitance in the case of thicker NMs, as will be further proved in following CP results. A reduction peak at ~0.2 V can be clearly observed in all the electrodes and is associated with intraband gap localized states [44, 45]. In addition, we also measured CV curves of electrode made from TiO$_2$ NMs with 100 ALD at different scan rates, and the results are shown in Fig. 3b. A redox peak shifting behavior (from higher to lower potential) is connected with the change in intercalation/deintercalation of M$^+$ ions and synergetic effect [46, 47]. Briefly, limited diffusion and charge transfer rate at a higher scan rate lead to corresponding shift [48, 49]. In order to further illustrate the charging/discharging behavior, the galvanostatic charge/discharge curves of TiO$_2$ NMs electrodes at different current densities within a potential range of 0–0.5 V are shown in Fig. 3c, d and Additional file 1: Figure S4. The nonlinear curves of CP represent the pseudocapacitor function, which is consistent with the CV curves, and represent the Faradaic behavior. It should be noted that the discharge time of TiO$_2$ NMs electrode with 100 ALD cycles is notably prolonged compared with TiO$_2$ NMs electrodes with 200 and 400 ALD cycles, indicating the largest specific capacitance value. However, ultra-thin NMs electrode exhibit high gravimetric specific activity but cannot afford large current due to the limited number of active sites [50]. The extended charging/discharging times of TiO$_2$ NMs electrodes with 100, 200, and 400 ALD cycles at current density of 1 A/g means that reduction/oxidation reactions take place (mainly on surfaces of NMs) during the process, which is the property of pseudocapacitor [51].
Figure 4 (a) shows the specific capacitances of electrodes made from TiO$_2$ NMs with 100, 200, and 400 ALD cycles at different current densities ranging from 1 to 5 A/g. Specific capacitances of 2332, 1780, 1740, 1720, and 1690 F/g are obtained from TiO$_2$ NMs with 100 ALD cycles, 1660, 1300, 1182, 1104, and 1040 F/g from TiO$_2$ NMs with 200 ALD, and 1094, 848, 732, 672, and 630 F/g from TiO$_2$ NMs with 400 ALD cycles. In previous literature, Yang et al. [43] prepared the TiO$_2$/N-doped graphene composite structure with a capacitance of 385.2 F/g at 1 A/g and 320.1 F/g at 10 A/g. Zhi et al. [52] reported a specific capacitance of 216 F/g for TiO$_2$ nanobelts with nitrogen doping. Di et al. [53] fabricated TiO$_2$ nanotubes decorated with MnO$_2$ nanoparticles and a specific capacitance of 299 F/g at a current density of 0.5 A/g was obtained. Obviously, the capacitance of the electrode made from current TiO$_2$ NMs is much higher. Moreover, the energy and power density relation of the three electrodes are shown in Fig. 4b and Additional file 1: Table S1. Energy density is the capacity of energy storage devices and power density is their ability to deliver it, and both are the key parameters used to evaluate the electrochemical performance of supercapacitors. Vividly, when current density increases from 1 to 5 A/g, TiO$_2$ NMs electrode with 100 ALD cycles possesses a high energy density of 81–57 Wh/kg compared to 59–36 Wh/kg of TiO$_2$ NMs electrode with 200 ALD cycles and 38–21 Wh/kg of TiO$_2$ electrode NMs with 400 ALD cycles, while the power density increases from 250 to 1250 W/kg (Fig. 4b). The high performance might be due to the mixture of anatase and rutile phases (Fig. 2) as this leads to surface passivation and increased ion transportation [54–56]. In addition, the enlarged surface area of the TiO$_2$ NMs and interconnectivity among the NMs also cause the enhancement in ions transportation. On the other hand, we believe that the decrease in electrochemical performance with the increasing ALD
cycles is mainly due to the decreased NM/electrolyte interface area if the masses of the active materials are the same. Moreover, the TiO$_2$ NMs with more ALD cycles (i.e., thickness) is stiffer and flat (see Fig. 1), and therefore, the overlap between the NMs is obvious. This may limit the surface access for electrolyte ions, resulting in dead volume, high resistance, and reduced capacitance [57]. In addition, with the increase of current densities, the diffusion rate of electrolyte might not be enough to satisfy the electrochemical reaction of electrode material, and therefore, a decrease of capacitance with current density can be observed in Fig. 4a [39, 40]. In order to further reveal the electrochemical properties of the current TiO$_2$ NMs electrodes, EIS characterizations was carried out because EIS can provide the information about electrode-electrolyte and electrode internal resistance [58]. Figure 4c demonstrates the EIS results of all three electrodes, and the horizontal intercept indicates the internal resistance of pseudocapacitor. It is clearly observed that TiO$_2$ NMs electrode with 400 ALD cycles possesses high internal resistance as compared to TiO$_2$ NMs electrodes with 200 and 100 ALD cycles. We consider that the increased resistance of TiO$_2$ NMs electrode with 400 ALD cycles is mostly by reason of increased NM thickness since the TiO$_2$ has relatively large resistivity [39, 48]. The TiO$_2$ NMs with 100 ALD cycles exhibits the lowest internal resistance compared with others because the large surface area allows the better ions passage [59] and flexibility of thin NM improves the interlayer connection with decreased resistivity. All these results demonstrate that thin TiO$_2$ NMs with high electroactivity are promising electrode materials for high-performance pseudocapacitor. In order demonstrate the potential application of TiO$_2$ NMs supercapacitor, four electrodes made from TiO$_2$ NMs with 100 ALD cycles were assembled into two symmetrical supercapacitors, i.e., each supercapacitor consisted of two

![Fig. 4](image-url)
electrodes of TiO₂ NMs with 100 ALD cycles. The two supercapacitors were connected in series and then charged at 5 A/g current density to 0.5 V. Afterwards, they were used to light up a red LED (light-emitting diode) with working voltage of ~1.5 V and the LED emitted light for ~1 min (see Fig. 4d and Additional file 2: Video S1). The cycle stability of the electrode made from TiO₂ NMs with 100 ALD cycles was also studied and the results are shown in Additional file 1: Figure S5. A capacitance retention of 80.98% is observed after cycling at 5 A/g for 40 charge/discharge cycles, suggesting a less interaction of electrolyte ions with electrode surface after repeated cycles. We believe that the performance of the NMs electrode might be further promoted if the conductivity of the NMs is increased. With the help of the ALD technique, the conductivity of the NMs can be increased by fabricating multi-layered NMs where materials with high conductivity are incorporated. More works are currently in progress.

Conclusion
In summary, we have fabricated TiO₂ NMs for electrodes of supercapacitor, and the electrochemical performance of the NMs was studied in detail. The TiO₂ NM electrode demonstrates increased capacitance with decreased NM thickness. At a current density of 1 A/g, the specific capacitance of 2332 F/g is obtained for TiO₂ NM with 100 ALD cycles, and the corresponding energy density is calculated to be 81 Wh/kg. The enhancement of the performance is mainly attributed to the fabrication strategy and the ultra-thin feature of NMs, because the large surface area and short diffusion path of NMs facilitate ion transport through electrode/electrolyte interface. The interconnectivity among the NMs also remarkably enhances the ion transportation in the electrode. We also demonstrate that two supercapacitors connected in series can power a LED, suggesting the application potential of TiO₂ NMs supercapacitor. The current facile design opens the way to build NMs electrodes for next-generation wearable energy storage devices at low-cost. However, for practical applications of NM-based structures in future supercapacitors, further studies are required.
