Abstract
We report analytical and numerical results on breather-like field configurations in a theory which is a deformation of the integrable sine-Gordon model in (1 + 1) dimensions. The main motivation of our study is to test the ideas behind the recently proposed concept of quasi-integrability, which emerged from the observation that some field theories possess an infinite number of quantities which are asymptotically conserved in the scattering of solitons, and periodic in time in the case of breather-like configurations. Even though the mechanism responsible for such phenomena is not well understood yet, it is clear that special properties of the solutions under a space-time parity transformation play a crucial role. The numerical results of the present paper give support for the ideas on quasi-integrability, as it is found that extremely long-lived breather configurations satisfy these parity properties. We also report on a mechanism, particular to the theory studied here, that favours the existence of long lived breathers even in cases of significant deformations of the sine-Gordon potential. We also find numerically that our breather-like configurations decay through the gradual increase of their frequency of oscillations.

1. Introduction

Solitons play a fundamental role in the study of non-linear phenomena because in many situations they can be considered as the ‘normal modes’ of the physical system in the strong coupling regime. In fact, in special examples of gauge theories in \((3 + 1)\) dimensions and integrable field theories in \((1 + 1)\) dimensions, there exist duality relations interchanging the roles of the fundamental excitations of the fields at weak coupling, and the solitons at the strong coupling regime [1]. In \((1 + 1)\) dimensions, where soliton theory is much better understood, the solitons are often described as those classical solutions that propagate without dissipation and dispersion, and when two of such solitons are scattered they do not destroy each other. The only effect of their scattering is a shift in their positions in relation to the values they would have had, had they not participated in this scattering process. The most acceptable explanation for such behaviour is that, in practically all known soliton theories, there exists an infinite number of conserved quantities that dramatically constrains the dynamics, and leaves no options for the solitons after the scattering but to continue being themselves. Of course, here we talk only about genuine solitons (which in their scattering with each other do not radiate etc). This is a remarkable fact but it certainly has an annoying drawback. It forces solitons to exist only in the realm of the so-called exactly integrable field theories in \((1 + 1)\) dimensions. Such theories are, however, very special as they possess highly non-trivial hidden symmetries and they have been used as convenient laboratories to study non-perturbative phenomena and so have lead to the development of new and important techniques in field theories. Of course, there exist many non-integrable theories which also possess one soliton structures (topological or not). Such solitons can be stable for small perturbations (this is particularly true for topological solitons) but, to our knowledge, only integrable models possess field configurations describing two interacting and non-radiating solitons; i.e. which in their scattering process only undergo the above mentioned shift in their positions.

Recently we have observed that some non-integrable field theories in \((1 + 1)\) dimensions, present properties similar to those of exactly integrable theories [2–4]. They have soliton-like field configurations that behave in a scattering process in a very similar way to the true solitons, i.e. they do not destroy each other but could emit some energy and slow down etc. We have also found that such theories often possess an infinite number of quantities which are not exactly conserved in time, but are, however, asymptotically conserved. By that we mean that the values of these quantities do change, and change a lot, during their scattering process but then they return, after the scattering, to the values they have had before it. This is a remarkable property since from the point of view of the scattering what matters are the asymptotic states, and so such a theory looks a bit as an effective integrable theory. We have also observed that some of such non-integrable theories possess breather-like solutions that are extremely long-lived, i.e. they oscillate without loosing much energy through radiation for very long periods of time. In addition, each one from this infinite number of ‘almost conserved’ quantities, when evaluated on these breather-like field configurations, does vary in time but in a steady way by oscillating between two fixed values. For these reasons we have named this phenomenon quasi-integrability. The mechanisms responsible for these remarkable properties are not fully understood yet, but we believe they will play a very important role in the study of many non-linear phenomena. Since exactly integrable theories are rare and in general do not describe realistic physical phenomena, the quasi-integrable theories may be very useful in their description of more realistic physical processes.

Of course, similar ideas have been around for some time now. KAM theory for PDEs has started around 1990, and developed quite a lot since then (see for example [5–6]). However, most of KAM theory has dealt with PDEs in one spatial dimension. In [6] the author considers
a model close to the nonlinear Schrödinger equation used in mathematical physics and then shows that many properties of the solution of this equation are not altered significantly by small perturbations of the original equation. In addition, the main novelty of [6] lies in the fact that the model used for this study is defined in two and three spatial dimensions. These interesting analytical results clearly demonstrate that the ideas of generalising KAM theory to some PDEs, and in particular PDEs that often arise in mathematical and theoretical physics is not a hopeless task and it may help to explain some physical phenomena. The reading of this paper clearly shows that to say anything definitive in this area will be very difficult and will require sophisticated analytical tools.

More relevant to this paper is a recent paper by Martel and Merle [7] in which the authors show that a quartic gKdV equation does not possess a global pure 2-soliton solutions and that the collision of these solitons is inelastic. This interesting and very lengthy paper (100 pages) is very difficult to read but the result is very clearly stated. But the result is asymptotic and it is difficult to deduce from it whether its solitons will radiate, say, of their energy in few units of time or whether one would have to wait for this the life-time of the universe. But, of course, the fact that one can say something very definitive is very important though the practical, ‘physical’ relevance of this result is much less clear cut. So perhaps, one could combine this, very analytical, work with some numerical studies to get a better ‘feel’ for this radiation phenomenon.

In our paper we look at the models which generalise physically relevant sine-Gordon model. Our interest in these models in based on their physical relevance and in this case the issue of asymptotic behaviour of the structures and/or their life-times (if they are unstable) becomes very important. In the case of breathers an interesting paper of Kruskal and Segur [8] claimed that the sine-Gordon model was very unique, in a class of models with analytical potentials, in that it had stable breathers and many people think that this is associated with the model’s integrability. So then the question arises as to what happens when the model is perturbed. In this paper we study perturbations which preserve the existence of single topological kinks or anti-kinks and in which the initial breather-like are contructed as bound-like states of such kinks and anti-kinks. As all perturbed models possess exactly known single kink states the perturbations do not have to be very small.

Other perturbations of breather-like structures have also been studied by many analysts and we would like to draw attention of the reader to the papers by Denzler [9] and [10]. He, in the first of these very interesting papers, analyses perturbations of the sine-Gordon breather by analysing properties of the sine-Gordon breather-like solutions of the equation of the form

$$
\frac{\partial\psi}{\partial t} - \frac{\partial^2 \psi}{\partial x^2} + \sin(\psi) = \epsilon \Delta(\psi, \epsilon) = \epsilon \Delta(0, \epsilon) + O(\epsilon^2),
$$

(1.1)

where $\Delta(\psi, 0) = g(\psi)$ is an analytic function of $\psi$, and $\Delta(0, \epsilon) = 0$ for all $\epsilon$. He finds, that to the first order in $\epsilon$ the sine-Gordon breather is stable (for any frequency of the breather) if $g(\psi)$ takes the form

$$
g(\psi) = \frac{1}{4}(1 - 4 \cos(\frac{\psi}{2}) + 3 \cos(\psi) + 4 \cos(\psi) \log(\cos(\frac{\psi}{4})))
$$

(1.2)
or is obtained by a rescaling of $x$ and $t$.

The second paper considers other perturbations also studied to the first order in $\epsilon$ and its very involved calculations show that the breather is stable only for one frequency. Both these results, and some other ones, show that the problem of stability of breathers is very challenging and it is extremely difficult to get reliable results. And these results are valid also only to the lowest nontrivial order in the perturbation parameter. In fact in [2] we have also considered a perturbative approach to our problem but we failed to solve the resultant equations. Hence, here, we restrict our attention to a more numerical approach—to get some feeling on how fast
our quasi-breather fields decay, to prove the stability of the whole problem and we hope that our results will restimulate more analytical interest in this field.

In this paper we report some results of our numerical study of breather like field configurations in a \((1+1)\)-dimensional theory of a real scalar field \(\phi\) subjected to a potential which is a deformation of the sine-Gordon potential. This theory has already been considered in one of our previous papers [4], and the deformed potential depends on two free parameters \(\varepsilon\) and \(\gamma\). The parameter \(\varepsilon\) measures the deformation of the potential away from the sine-Gordon potential. The \(\gamma\)-parameter, when different from zero, makes the potential not symmetrical under the reflection \(\phi \rightarrow -\phi\). In [2, 4] we have argued that the phenomenon of quasi-integrability may be related to some properties of the two-soliton and breather field configurations under a very specific space-time parity transformation. When the field \(\phi\), evaluated on such configurations, is odd under this parity transformation, we have an infinite number of quasi-conserved quantities, i.e. quantities which are asymptotically conserved in the case of two-soliton solutions and oscillate in time for breather-like configurations. In order to have this property the potential has to be even under the change \(\phi \rightarrow -\phi\). Thus, we would expect the cases when \(\gamma \neq 0\) to be less integrable than the cases with \(\gamma = 0\). Our numerical simulations do confirm this expectation, but we also observe an effect which had not been foreseen. Due to the way we build our initial field configuration, for the numerical simulations, from the exact sine-Gordon breather solution, the initial kinetic energy decreases with the increase of the \(\varepsilon\)-parameter, and so does the amplitude of oscillations of the resulting breather-like configurations in the deformed theory. This makes this quasi-breather field to oscillate in a region where the deformed potential differs little from the sine-Gordon potential. So, we find that we can have very long lived breather-like fields for theories which are (globally) large deformations of the integrable sine-Gordon model.

The paper is organized as follows. In section 2, for completeness, we present our ideas about quasi-integrability based on a anomalous quasi-zero curvature condition (Lax equation), and give the algebraic and dynamical arguments of why the properties of the initial field configurations under this space-time parity transformations are important for the quasi-integrability concept. In section 3 we present the results of our numerical simulations. They have involved using the 4th order Runge–Kutta method to simulate the time dependence of field configurations which would allow us to determine and study various properties of breather-like solutions of the full equations of motion of our models for several choices of values of the parameters \(\varepsilon\) and \(\gamma\) characterizing the potential. In the last section (section 4) we present an overview of our results and make a plea for further work in this area and making a connection with the previously obtained more analytical work.

2. The model and the concept of quasi-integrability

In this paper we report some results of our numerical simulations to study breather-like solutions of one of such quasi-integrable theories which corresponds of a particular deformation of the sine-Gordon model introduced in [4]. It is a \((1+1)\) dimensional theory of a real scalar field \(\phi\) described by the Lagrangian

\[
L = \frac{1}{2} \left[ (\partial_\tau \phi)^2 - (\partial_\xi \phi)^2 \right] - V(\phi),
\]

where the potential depends on two real parameters \(\varepsilon\) and \(\gamma\) and is given by

\[
V(\phi) = \frac{1}{2} \left[ 1 + \varepsilon \phi(\phi - 2\gamma) \right]^3 \sin^2[\psi(\phi)],
\]

\(1625\)
where
\[ \psi(\phi) = \frac{c\phi}{\sqrt{1 + \epsilon\phi(\phi - 2\gamma)}}. \quad (2.3) \]
and
\[ c = \sqrt{1 + \epsilon\pi(\pi - 2\gamma)}. \quad (2.4) \]

Note that for \( \epsilon = 0 \), one gets \( c = 1, \psi = \phi \), and the potential (2.2) reduces to the sine-Gordon potential
\[ V_{SG} = \frac{1}{2} \sin^2(\psi). \quad (2.5) \]

Thus, the theory (2.1), for \( \epsilon = 0 \), reduces to the sine-Gordon model defined by the Lagrangian
\[ L_{SG} = \frac{1}{2} [\partial_\psi^2 - (\partial_\phi^2)] - V_{SG}. \quad (2.6) \]

The vacua of the sine-Gordon theory is obviously given by the constant field configurations \( \psi = n\pi \), with \( n \) integer. The theory (2.1) also has infinitely many degenerate vacua but not equally spaced like in the sine-Gordon case. However, the parameter \( c \) given in (2.4), was chosen to preserve two of these vacua. Indeed, \( \psi(\phi = 0) = 0 \) and \( \psi(\phi = \pi) = \pi \). The parameter \( \gamma \) is important in our analysis of the quasi-integrability properties of the theories (2.1).

Note that the potential (2.2) is even under the transformation \( \phi \rightarrow -\phi \) for the case \( \gamma = 0 \), i.e. \( V_{\gamma=0}(-\phi) = V_{\gamma=0}(\phi) \) but not otherwise. As we will discuss below the quasi-integrability properties is favoured in the cases when \( \gamma = 0 \). In figure 1 we show the potential (2.2) for some values of \( \epsilon \) and \( \gamma \).

The potential (2.2) was introduced in [4] using the techniques of [11, 12] based on ideas of self-dual or BPS solutions. Indeed, the static one-soliton solutions of the sine-Gordon model (2.6) given by
\[ \psi = 2 \text{ArcTan}(e^{\pm x}) \quad (2.7) \]
satisfy the BPS equation
\[ \partial_\phi \psi = \pm \sqrt{2 V_{SG}} \quad (2.8) \]
In fact, any static solution of the first order BPS equation (2.8) is a solution of the second order Euler–Lagrange (sine-Gordon) equation following from (2.6). If one now introduces a field transformation \( \psi(\phi) \), it follows that the new field \( \phi \) satisfies the BPS equation
\[ \partial_\phi \phi = \pm \sqrt{2 V} \quad (2.9) \]
with the potential being given by
\[ V = \frac{V_{SG}}{\left(\frac{4\psi}{\pi}\right)^2}. \quad (2.10) \]

The potential (2.2) has been obtained from (2.10) by the field transformation (2.3). It then follows that the static solutions of (2.9) are solutions of the theory (2.1). Indeed, the static one-soliton solutions of (2.1) are obtained from (2.7) by applying the transformation (2.3). The transformation \( \psi(\phi) \) maps BPS solutions of the sine-Gordon model (2.6) into BPS solutions of the theory (2.1). Note, however, that in general, a given solution of the second order
The equation of motion of the sine-Gordon model is not necessarily mapped into a solution of the second order Euler–Lagrange equation corresponding to (2.1).

The concept of quasi-integrability does not really depend upon the fact that the quasi-integrable theories are obtained from the integrable ones by field transformations of the type described above. However, many aspects of our analysis get simplified by using such a connection between integrable and non-integrable theories. In particular, the initial configurations used in our numerical simulations for breathers, have been obtained by applying the field transformation (2.3) to the exact breather solutions of the sine-Gordon model.

As described in [2, 4] our concept of quasi-integrability involves a connection $A_\mu$ satisfying an anomalous zero-curvature condition. Indeed, let us consider the connection or Lax potentials given by

$$A_+ = \frac{1}{2} \left[ (\omega^2 V - m) b_1 - i \omega \frac{dV}{d\phi} F_0 \right],$$

$$A_- = \frac{1}{2} b_{-1} - \frac{i}{2} \omega \partial_\phi F_0,$$

where we have used light-cone variables

$$x_\pm = \frac{1}{2} (t \pm x) \quad \text{with} \quad \partial_\pm = \partial_x \pm \partial_t \quad \text{and} \quad \partial_\phi \partial_\phi = \partial_t^2 - \partial_x^2 \equiv \partial^2.$$

The quantities $b_\mu$ and $F_\alpha$ appearing in (2.11) are generators of the $sl(2)$ loop algebra defined as

$$b_{2k+1} = \lambda^k (T_+ + \lambda T_-), \quad F_{2k+1} = \lambda^k (T_+ - \lambda T_-), \quad F_{2k} = 2 \lambda^k T_0,$$

where $\lambda$ is the so-called spectral parameter of the loop algebra, and $T_0, T_\pm$ are the generators of the finite $sl(2)$ algebra:

$$[T_0, T_\pm] = \pm T_\pm, \quad [T_+, T_-] = 2 T_0.$$

It is then easy to see that the curvature of the connection (2.11) is given by

$$F_+ \equiv \partial_\phi A_- - \partial_t A_+ + [A_+, A_-] = X F_0 - \frac{i}{2} \omega \left[ \partial^2 \phi + \frac{\partial V}{\partial \phi} \right] F_0$$

Figure 1. Plot of the potential $V(\phi)$, given in (2.2), as a function of $\phi$ for $\varepsilon = 0.0$ (solid line), $\varepsilon = 0.01$ (dashed line), $\varepsilon = 0.2$ (dotted line) and $\varepsilon = 0.3$ (dot–dashed line). The plots on the left correspond to $\gamma = 0$, and those on the right to $\gamma = 0.2$. Note that $V(\phi)$ is invariant under the change $\phi \to -\phi$ for the case $\gamma = 0$, but not otherwise. In addition, the vacua $\phi = 0$ and $\phi = \pi$ are common to all values of $\varepsilon$ and $\gamma$. For $\varepsilon = 0$ the peaks of the potential grow in height, compared to those for $\varepsilon = 0$, for $|\phi| > \pi$, irrespective of the value of $\gamma$. 

with

\[ X = \frac{i \omega}{2} \partial_\phi \left[ \frac{\partial^2 V}{\partial \phi^2} + \omega^2 V - m \right]. \] (2.16)

Note that the Euler–Lagrange equation following from (2.1) for a general potential \( V \) is given by

\[ \partial^2 \phi + \frac{\partial V}{\partial \phi} = 0. \] (2.17)

Thus, the term proportional to the Lie algebra generator \( F_0 \) vanishes when the field configurations satisfy the equation of motion (are 'solutions' of the theory). For the case of the sine-Gordon model potential

\[ V_{sg} = \frac{m}{\omega^2} [1 - \cos(\omega \phi)] = \frac{2m}{\omega^2} \sin^2\left(\frac{\omega}{2} \phi\right); \] (2.18)

the remaining term in (2.15), i.e. the anomaly \( X \) given in (2.16), vanishes. In such a case the curvature (2.15) vanishes for sine-Gordon solutions and this is what makes the sine-Gordon model integrable. For the potential (2.2) however, the anomaly \( X \) does not vanish irrespective of the choice of values of the parameters \( \omega \) and \( m \) (except for the trivial case \( \omega = 0 \)).

The infinite number of quantities conserved asymptotically can be constructed using the techniques adapted from those of the integrable field theories. This can be done as follows. We perform the gauge transformation [4]

\[ A_\mu \to a_\mu = gA_\mu g^{-1} - \partial_\mu g g^{-1} \quad \text{with} \quad g = \exp \left[ \sum_{n=1}^{\infty} \zeta_n F_n \right]. \] (2.19)

The parameters \( \zeta_n \) in \( g \) can then be chosen recursively starting from \( n = 1 \) onwards in such a way that the component \( a_- \) of the transformed connection has only terms in the direction of the generators \( b_{2m+1} \). So these terms generate an infinite dimensional abelian subalgebra of the \( sl(2) \) loop algebra.

Note that due to the non-vanishing anomaly \( X \) the component \( a_+ \) has also terms in the direction of the generators \( b_{2m+1} \) and \( F_m \) as well. For an integrable theory, like the sine-Gordon one, the anomaly \( X \) does vanish and the terms proportional to \( F_m \) in \( a_+ \) vanish too, and the whole connection can be made to lie in the abelian subalgebra generated by \( b_{2m+1} \). In the general case, i.e. when the anomaly does not vanish, the transformed curvature becomes

\[ F_+ \to gF_+ g^{-1} = \partial_+ a_- - \partial_- a_+ + [a_+, a_-] = XgF_1 g^{-1}, \] (2.20)

where we have used the equation of motion (2.17). Note that the commutator of any \( b_{2m+1} \) with any given \( F_n \) produces terms proportional to the \( F_m \) generators only. Therefore, for every component of the transformed curvature (2.20) in the direction of a given \( b_{2m+1} \) we get an equation of the form

\[ \partial_n a_+^{(2n+1)} = \partial_\phi a_-^{(2n+1)} \gamma_n^{(2n+1)} \] (2.21)

with \( a_+^{(2n+1)} \) and \( \gamma_n^{(2n+1)} \) being the coefficients of the generators \( b_{2m+1} \) in the expansion of \( a_\pm \) and \( g F_1 g^{-1} \), respectively, in terms of the elements of the basis of the \( sl(2) \) loop algebra.

The relations (2.21) constitute an infinite number of anomalous conservation laws. Indeed, by re-expressing them in the \( x \) and \( t \) components (see (2.12)) one gets the relations

\[ \frac{dQ_n^{(2n+1)}}{dt} = -\frac{1}{2} \alpha_{(2n+1)}, \] (2.22)
The charges $Q^{(2n+1)}$ are not conserved due to the non-vanishing anomaly $X$. They would, of course, be conserved in an integrable theory like the sine-Gordon one for which $X = 0$.

Note, however, that traveling solutions i.e. those which can be set at rest by a $(1 + 1)$ dimensional Lorentz transformation the charges $Q^{(2n+1)}$ are conserved. To see this we observe that in the rest frame the charges are obviously $x$-dependent only, and so from (2.22) one gets $\alpha^{(2n+1)} = 0$. But from (2.21) one finds that $X^{(2n+1)}$ is a pseudo-scalar in $(1 + 1)$ dimensions, and so $\alpha^{(2n+1)}$ vanishes in any Lorentz frame. Therefore, for traveling solutions like the one-soliton solutions, the charges $Q^{(2n+1)}$ are conserved even in non-integrable theories.

Next we note a striking property that helps us to define what we mean by a quasi-integrable theory. For some very special subsets of solutions of the theory (2.1) the charges $Q^{(2n+1)}$ satisfy what we call a mirror symmetry. For any one of the solutions in such a subset one can find a special point $(\Delta t, \Delta x)$ in space-time, and define a parity transformation around this point:

$$P : (\tilde{x}, \tilde{t}) \rightarrow (-\tilde{x}, -\tilde{t}) \quad \text{with} \quad \tilde{x} = x - x_\Delta, \quad \tilde{t} = t - t_\Delta,$$

(2.24)

The field $\phi$ corresponding to such a solution is odd under such parity, i.e.

$$\phi \rightarrow -\phi + \text{const.}$$

To find the implications of this observation we combine our parity transformation with the following order two automorphism of the $sl(2)$ loop algebra:

$$\Sigma(b_{2n+1}) = -b_{2n+1}, \quad \Sigma(F_{2n}) = -F_{2n}, \quad \Sigma(F_{2n+1}) = F_{2n+1}$$

(2.26)

to build a $\mathbb{Z}_2$ transformation $\Omega \equiv P \Sigma$, as the composition of a space-time and internal $\mathbb{Z}_2$ transformations. It turns out that the $A_-$ component of the connection (2.11) is odd under such $\mathbb{Z}_2$ transformation, i.e. $\Omega(A_-) = -A_-$. This fact can be used to show that the group element $g$ used to perform the gauge transformation (2.19) is even, i.e. $\Omega(g) = g$. Then, one can use this fact to show that the factor $\gamma^{(2n+1)}$ in the integrand of $\alpha^{(2n+1)}$ is odd under the space-time parity, i.e. $P(\gamma^{(2n+1)}) = -\gamma^{(2n+1)}$. More details of this reasoning can be found in [4].

If we now assume that the potential $V(\phi)$ in (2.1) is even under the parity when evaluated on the special solutions satisfying (2.25), i.e. $P(V) = V$, then it follows that the anomaly $X$, given in (2.16), is also even, i.e. $P(X) = X$. Therefore we get that

$$\int_{-\tilde{t}_0}^{\tilde{t}} dt \int_{-\tilde{x}_0}^{\tilde{x}_0} dx \, X^{(2n+1)} = 0,$$

(2.27)

where the integration is performed on any rectangle with center in $(t_\Delta, x_\Delta)$, i.e. $\tilde{t}_0$ and $\tilde{x}_0$ are any given fixed values of the shifted time $\tilde{t}$ and space coordinate $\tilde{x}$, respectively, introduced in (2.24). Now, by taking $\tilde{t}_0 \rightarrow \infty$, we conclude that the charges (2.23) satisfy the following mirror time-symmetry around the point $t_\Delta$:

$$Q^{(2n+1)}(t = \tilde{t}_0 + t_\Delta) = Q^{(2n+1)}(t = -\tilde{t}_0 + t_\Delta) \quad n = 0, 1, 2, \ldots$$

(2.28)

That is a remarkable property for the special subsets of solutions satisfying (2.25) and belonging to a theory of type (2.1) with an even potential under the parity (2.24). Such subset of solutions defines our quasi-integrable theory. For the case of two-soliton solutions one note that by taking the limit $\tilde{t}_0 \rightarrow \infty$, one gets that the charges are asymptotically conserved, i.e. have the same values before and after the scattering.
For the case of sine-Gordon theory it is true that for any two-soliton solution or breather solution it is possible to find a point in space-time \((\Delta t, \Delta x)\), such that the solution is odd under a parity transformation around such point. Let us now consider the theory (2.1) with the potential (2.2) and expand its solutions in powers of the parameter \(\varepsilon\) around a given solution of the sine-Gordon model \(\phi_0^{-}\) which is odd under the parity

\[
\phi = \phi_0^{-} + \varepsilon \phi_1 + \varepsilon^2 \phi_2 + \ldots.
\]  

(2.29)

We now split the higher order solutions in even and odd parts as

\[
\phi_n^{(\pm)} \equiv \frac{1}{2}(1 \pm P) \phi_n
\]  

(2.30)

It turns out that for the case where \(\gamma = 0\), the equations of motion for the first order solution are of the form

\[
\partial^2 \phi_1^{(+)} + \frac{\partial^2 V}{\partial \phi^2} |_{\phi=0} \phi_1^{(+)} = 0,
\]

\[
\partial^2 \phi_1^{(-)} + \frac{\partial^2 V}{\partial \phi^2} |_{\phi=0} \phi_1^{(-)} = f_1(\phi_0^{(-)})
\]  

(2.31)

That means that the odd part of the first order solution \(\phi_1^{(-)}\) satisfies a non-homogeneous equation and so it can never vanish. On the other hand the even part \(\phi_1^{(+)}\) satisfies a homogeneous equation and so it can vanish. In fact, if \(\phi_1\) is a solution, so is \(\phi_1 - \phi_1^{(+)} = \phi_1^{(-)}\). Therefore, one can always choose a first order solution which is odd under the parity. If one makes such choice then it turns out that the second order solution has similar properties, i.e. \(\phi_2^{(-)}\) satisfies a non-homogeneous equation and \(\phi_2^{(+)}\) a homogeneous one. Then one can again choose the second order solution to be odd, and the process repeats in all orders. For a detailed account of that please see [4]. Such argument works for the potential (2.2) with \(\gamma = 0\) but not otherwise. Therefore, we can say that the theory (2.1) with the potential (2.2) with \(\gamma = 0\) possesses subsets of solutions which constitute a quasi-integrable theory. Those are the facts that we want to check with our numerical simulations which we now explain.

3. The numerical simulations

Our numerical simulations were performed using the 4th order Runge–Kutta method of simulating time evolution. As in [4] we experimented with various grid sizes and numbers of points and most simulations were performed on lattices of 10001 lattice points with lattice spacing of 0.01 (so they covered the region of \((-50.0, 50.0)\). Time step \(dt\) was 0.0001.

The breather-like structures were placed at \(x \sim 0\) and stretched up \(\pm 20.00\) from their positions hence at the edges of the grid the fields resembled the vacuum configurations which were modified only by waves that were emitted during the scattering.

At the edges of the grid (i.e. for \(49.50 < |x| < 50.00\)) we absorbed the waves reaching this region (by decreasing the time change of the magnitude of the field there).

In consequence, the total energy was not conserved but the only energy which was absorbed was the energy of radiation waves. Hence the total remaining energy was effectively the energy of the field configuration which we wanted to study.

Our choice of boundary conditions was motivated by our desire to see whether the system radiates some energy out or not and if it does how fast this process is. Of course, we could have
used other boundary conditions (like reflecting ones). They would not be useful in our case as the reflected waves, if there were any, would have then interacted with the breather-like structures possibly destabilising them further. As we were checking whether the system allows the existence of quasi-breathers the absorbing boundary conditions were the most appropriate. And to decrease any reflection from the absorbing region we increased the absorption linearly as we moved towards the boundaries in the absorption region. We experimented with the magnitude of the absorption and have found that 10% absorption was sufficient to achieve our aims. Changing it had no significant effects and so most of our results were obtained with such absorption.

To start our simulations we took a breather configuration for the sine-Gordon model (3.1) and then performed the change of variables (2.3) to obtain the corresponding \( \phi \) field. We then used this field and its derivative at \( t = 0 \) as the initial conditions for the simulations.

The exact breather solution of the sine-Gordon model (2.6) is given by [13]

\[
\psi = 2 \text{ArcTan} \left[ \frac{\sqrt{1 - \nu^2}}{\nu} \sin \frac{\Gamma_k}{\cosh \Gamma_k} \right], \tag{3.1}
\]

where \( \nu \) is the speed of the breather, \( \nu \) its frequency \((-1 < \nu < 1)\) and

\[
\Gamma_k = \sqrt{1 - \nu^2} \frac{(x - \nu t)}{\sqrt{1 - \nu^2}}, \quad \Gamma_i = \nu \frac{(t - \nu x)}{\sqrt{1 - \nu^2}}. \tag{3.2}
\]

In all our simulations we looked at the time dependence of our breather-like field configurations initially at rest, i.e. with \( \nu = 0 \). Therefore, the initial configuration of the breather at \( t = 0 \), with \( \nu = 0 \) is

\[
\psi \bigg|_{t=0} = 0, \quad \frac{d\psi}{dt} \bigg|_{t=0} = \frac{2 \sqrt{1 - \nu^2}}{\cosh(\sqrt{1 - \nu^2} x)}. \tag{3.3}
\]

The input for our program is the initial configuration of the \( \phi \)-field defined by the transformation (2.3), and so

\[
\phi \bigg|_{t=0} = 0, \quad \frac{d\phi}{dt} \bigg|_{t=0} = \left\{ \frac{d\phi}{dt} \frac{d\psi}{dt} \right\} \bigg|_{t=0} = \frac{1}{\sqrt{1 + \varepsilon \pi(\pi - 2 \gamma)}} \frac{2 \sqrt{1 - \nu^2}}{\cosh(\sqrt{1 - \nu^2} x)}. \tag{3.4}
\]

From (2.1) we see that the initial energy of the breather-like configuration of the model was

\[
E = 2 \int_{-\infty}^{\infty} dx \left[ \frac{1}{2} \left[ (\partial_t \phi)^2 + (\partial_x \phi)^2 \right] + V(\phi) \right] \tag{3.5}
\]

The factor 2 in front of the integral was put to match the definition of the energy in the numerical code. For the initial configuration (3.4) we have \( \frac{d\phi}{dx} \bigg|_{x=0} = 0 \), and \( V(\phi = 0) = 0 \) (see (2.2)), and so the initial energy was

\[
E = \frac{8 \sqrt{1 - \nu^2}}{\left[ 1 + \varepsilon \pi(\pi - 2 \gamma) \right]}. \tag{3.6}
\]

Note that the energy of the initial configuration has the same \( \nu \)-dependence as the sine-Gordon breather, but it is re-scaled by the factor \( 1/\varepsilon c^2 \), with \( c \) given by (2.4), and so it decreases with the increase of the deformation parameter \( \varepsilon \). This rescaling factor and its decrease with \( \varepsilon \) has an interesting effect as we will demonstrate in the discussions of the simulations.
We have performed several simulations for different values of the frequency of the breather i.e. $\nu$ in (3.1) and for various values of $\varepsilon$ and $\gamma$. For some of these simulations we have also calculated the anomaly of the first non-trivial quasi-conserved charge given in (2.23), namely $\alpha^{(3)}$ and $Q^{(3)}$. We have chosen in the Lax potentials (2.11) the parameters $\omega = 2$ and $m = 1$. The reason for this choice was that those are the values that make the sine-Gordon potential (2.18), for which the anomaly (2.16) vanishes, equal to (2.5) when $\varepsilon$ is set to zero. Then from (2.21) we find that

$$\gamma^{(3)} = i 2 \partial^2 \phi.$$  

(3.7)

Thus, using (2.23) and (2.16), we see that

$$\alpha^{(3)} = -2 \int_{-\infty}^{\infty} dx \partial_x \phi \partial^2 \phi \left[ \frac{d^2 V}{d\phi^2} + 4V - 1 \right].$$

(3.8)

We have also computed what we called ‘the time integrated anomaly’ given by (see (2.22))

$$\beta^{(3)} = -\frac{1}{2} \int_{t_0}^{t} dt' \alpha^{(3)} = Q^{(3)}(t) - Q^{(3)}(t_0),$$

(3.9)

where $t_0$ is the initial time of the simulation, usually taken to be zero.

In the table below we summarise the main features of the simulations we had performed:

| Figure | $\varepsilon$ | $\nu$ | $\gamma$ | Initial energy (equation (3.6)) | Breather behaviour |
|--------|----------------|--------|----------|---------------------------------|-------------------|
| Figure 2 | 0.01 | 0.1 | 0 | 7.24 | Short lived |
| Figure 3 | 0.01 | 0.1 | 0.3 | 7.37 | Short lived |
| Figure 4 | 0.01 | 0.5 | 0 | 6.31 | Short lived |
| Figure 5 | 0.01 | 0.5 | 0.2 | 6.38 | Short lived |
| Figure 6 | 0.01 | 0.5 | 0.5 | 6.49 | Short lived |
| Figure 7 | 0.01 | 0.95 | 0 | 2.27 | Long lived |
| Figure 8 | 0.01 | 0.95 | 0.3 | 2.31 | Long lived |
| Figure 9 | 0.01 | 0.95 | 0.5 | 2.34 | Long lived |
| Figure 10 | 0.01 | 0.95 | 0.7 | 2.37 | Long lived |
| Figure 11 | 0.2 | 0.5 | 0 | 2.33 | Long lived |
| Figure 12 | 0.3 | 0.1 | 0 | 2.01 | Long lived |
| Figure 13 | 0.3 | 0.5 | 0 | 1.75 | Long lived |
| Figure 14 | 0.3 | 0.5 | 0.2 | 1.93 | Reasonably long lived |
| Figure 15 | 0.3 | 0.9 | 0 | 0.88 | Long lived |
| Figure 16 | 0.3 | 0.5 | 0.5 | 2.29 | Short lived |

In this table we have called some breather-like configurations short-lived and some long-lived. In fact these terms are not really well defined and a proper definition will require a lot of analytical work. Of course, this problem is related to a sensible definition of a ‘lifetime’ of a breather. This problem was first studied by Segur and Kruskal [8] and later looked at in more detail by Geicke [14]. More recently Fodor et al [15] generalised this work further and presented a general scheme which should allow us to discuss the rates of decay of quasi-breathers for a general class of models. This work is very impressive but quite complicated and we are planning to apply their technique to our breather-like structures. However, this will take some time to achieve so here we use the somewhat imprecise terms ‘short-lived’ and ‘long-lived’ based on the energy loss of the structure in 40 000 units of time. If during this time the loss of energy was more than 10% we would call such systems ‘short-lived’ and if it was less than 2% we would call them ‘long-lived’. In practice this choice is not very precise as many systems...
(specially those called ‘long-lived’) had an initial readjustment, which normally required some energy loss, followed by a very slow loss. This was further complicated by the movement instability (in many simulations sooner or later the breather-like configurations started to move, and always lost some energy when reflecting from the boundaries—more about this later) but, the division into two classes of behaviour was very clear-cut and interesting and hence we discuss it in some detail.

Looking the table and at the figures we can clearly observe two types of effects playing a role in the outcomes of the simulations:

First, as predicted by our analytical calculations based on the parity argument, the breathers for the cases with $\gamma = 0$ tend to live longer when compared to similar breathers for the cases where $\gamma \neq 0$. In order to see this more clearly, let us look at the simulations described by figure 10 all corresponding to $\varepsilon = 0.3$. The first plot (a) compares the dependence on $\nu$ but keeps $\gamma = 0$. The top curve corresponds to $\nu = 0.1$, the middle one to $\nu = 0.5$ and the bottom one to $\nu = 0.9$. The values of energy are clearly different (as we expect from (3.5)) we see that all breathers are ‘long-lived’. After the initial drop of energy the further drop is very small (but non-zero). In the second plot we compare the cases of $\gamma = 0$ and $\gamma = 0.2$ for $\nu = 0.5$ (the $\gamma = 0.2$ corresponds to the higher curve). We note that with our definition both breathers are ‘long-lived’ but the one with $\gamma = 0$ is ‘more’ long-lived; i.e. they both radiate energy very slowly but this small loss of energy is smaller for $\gamma = 0$. This is, of course, consistent with our expectations based on our ideas of quasi-integrability. These observations are reinforced further by what we see in figure 11, corresponding to the case $\gamma = 0.5$. In this case the energy drops much faster, and the breather starts moving after about $9 \times 10^4$ units of time, and it has bounced off the edges of the grid twice by $\sim 3 \times 10^5$. So, by increasing $\gamma$ the phenomenon we have called quasi-integrability, seems to have almost disappeared. Notice also that for smaller values of $\varepsilon$ the effect of $\gamma \neq 0$ is not so visible. However, we do notice in figures 2 and 3, corresponding to $\varepsilon = 0.01$ and $\nu = 0.1$, that the breather for $\gamma = 0.3$ is more short-lived when compared to that for $\gamma = 0$ (look at the energy decrease by $\sim 3.8 \times 10^5$). The same effect is visible in figures 4–6, corresponding to $\varepsilon = 0.01$ and $\nu = 0.5$. As the values of $\gamma$ are increased from 0.0 to 0.2 and then to 0.5, the emission of energy of the breathers increases. The same effect is not seem however in figures 7 and 8, corresponding to the case $\varepsilon = 0.01$ and $\nu = 0.95$. We cannot see much difference in the behaviour of their energies as the value of $\gamma$ is increased. The breather-like structures there seem to have stabilized quite well after
× 10^4 units of time. These cases might be feeling the influence of the second effect which we will now describe.

Looking at the table above one can easily spot a correlation between the values of the energy (3.6) of the initial configuration (3.4) used in the simulations, and the lifetime of the breathers. The higher the energy the shorter the lifetime of the breathers. In fact, we have started all our simulations with φ = 0 on all sites of the grid. The energy (3.6) corresponds to the total kinetic energy given to the initial configuration. Note that the potential energy is zero because V(φ = 0) = 0, and the elastic potential energy is also zero because ∂^2φ/∂x^2 = 0, on all sites of the grid at t = 0. So, the smaller is the initial kinetic energy, the smaller is the maximal value the φ-field can reach during the oscillations of the breather. Indeed, by departing from φ = 0 the potential energy V increases, as seen from the plot of the potential in figure 1. But if the value of φ remains small the breather oscillates only inside the part of the well of the potential around φ = 0 where V varies very little with ε. So, the breather can stay close to the breather solution of the sine-Gordon model which is integrable. Therefore, one would expect such a breather to live longer.

Indeed, we have looked at several simulations like those described in figures 7–10. They all had energies smaller than ∼ 2.3 and in all them the amplitude of oscillations of the field φ was never larger than 0.6. Not to have too many plots we do not present them here but only report that in all of them the time behaviour of the amplitudes was very similar (only decreasing extremely slowly with time). Moreover, the range of the initial amplitude was a little different (it decreased very slowly with the increase of γ (thus for γ = 0 it ranged from ∼ −0.6 to ∼ −0.6 while for γ = 0.7 it covered the range between ∼ −0.54 and ∼ 0.54. Incidentally, the values of the anomalies were also very similar in each case.

For these values of amplitudes one sees from figure 1 that the field φ does not reach regions where the potential departs significantly from the sine-Gordon potential. In all these cases the breathers live quite long, except for the case of figure 11 where γ = 0.5, and as discussed above the lack of good parity properties of the solution makes it short-lived. The dependence on γ only affects the initial drop of energy but is not very significant from the point of view
of whether the breather is long-lived or not. This is clearly seen from the cases involving initially high $\nu$ as shown in figures 7 and 8. All these cases correspond to $\gamma = 0, 0.3, 0.5$ and $0.7$, respectively. We note that all these breathers are long-lived. Their initial energies increase (but very little) with $\gamma$ and, in the initial evolution decrease more for larger $\gamma$ but then the decrease slows down and the breathers appear to be very long-lived. It would be interesting to check whether, at some stage, their energies ‘cross’ but the decrease is so slow and the gaps are still large enough that one would have to wait extremely long to observe this, if it ever happens, so this is not practical.

Figure 4. Breather’s simulation in the theory (2.1) with initial configuration (3.4), and with parameters given by $\varepsilon = 0.01$, $\nu = 0.5$ and $\gamma = 0.0$. The plots show the time dependence in the adimensional units of: the energy (a) and (b). The plot (b) shows the energy up to the moment just before when the quasi-breather has started moving. The plots (c) and (d) show the time dependence of the field $\phi$ at $x = 0$ in the grid at the beginning of the simulation (c) and at the time just before the soliton has started moving (d).
The only exception to our observation above is the case shown in figure 11 where \( \gamma = 0.5 \) (and \( \nu \) is smaller) and the effect of the lack of parity properties in this case, as discussed above, plays an important role and makes the breather to die faster. The fact that the energy (3.6) decreases with the increase of the value of \( \varepsilon \), makes it possible for us to find very long lived breathers for large values of \( \varepsilon \). Note that the increase of the frequency \( \nu \) of the initial configuration also plays a role in favouring the long lifetime of breathers since it decreases the value of the initial energy (3.6).

Figure 5. Breather’s simulation in the theory (2.1) with initial configuration (3.4), and with parameters given by \( \varepsilon = 0.01, \nu = 0.5 \) and \( \gamma = 0.2 \). The plots show the time dependence of (adimensional units): (a) the energy (3.5); (b) the field \( \phi \) at position \( x = 0 \) in the grid.

Figure 6. Breather’s simulation in the theory (2.1) with initial configuration (3.4), and with parameters given by \( \varepsilon = 0.01, \nu = 0.5 \) and \( \gamma = 0.5 \). The plots show the time dependence of (adimensional units): (a) the energy (3.5); (b) the field \( \phi \) at position \( x = 0 \) in the grid.
We have also observed a correlation among the anomaly $\alpha_3$, given in (3.8), and the integrated anomaly $\beta_3$ given in (3.9), with the life-time of the breather solutions. We do not present their plots as in each one of them the anomaly $\alpha_3$ oscillates steadily within a fixed interval. The integrated anomaly $\beta_3$, on the other hand presents a very slow drift of the order of one part in $10^4$ for $10^4–10^5$ units of time (see the right hand plot of figure 7). This is quite a long range of time integration, and it could well be inside the numerical errors which are difficult to estimate in these cases. This is also true in all the cases where the breathers appear to be long-lived. The plots of their anomalies look very similar and so they suggest that in all

Figure 7. Breather’s simulation in the theory (2.1) with initial configuration (3.4), and with parameters given by $\varepsilon = 0.01$, $\nu = 0.95$ and $\gamma = 0$. The plots show the time dependence of (in adimensional units): (a) the energy (3.5) and (b) the time integrated anomaly (3.9).

Figure 8. Breather’s simulation in the theory (2.1) with initial configuration (3.4), and with parameters given by $\varepsilon = 0.01$, $\nu = 0.95$. The plots compare the time dependence of the energy (3.5) (in adimensional units): form the three simulation corresponding to $\gamma = 0.3$ (lowest curve), $\gamma = 0.5$ (middle curve) and $\gamma = 0.7$ highest curve.

We have also observed a correlation among the anomaly $\alpha_3$, given in (3.8), and the integrated anomaly $\beta_3$ given in (3.9), with the life-time of the breather solutions. We do not present their plots as in each one of them the anomaly $\alpha_3$ oscillates steadily within a fixed interval. The integrated anomaly $\beta_3$, on the other hand presents a very slow drift of the order of one part in $10^4$ for $10^4–10^5$ units of time (see the right hand plot of figure 7). This is quite a long range of time integration, and it could well be inside the numerical errors which are difficult to estimate in these cases. This is also true in all the cases where the breathers appear to be long-lived. The plots of their anomalies look very similar and so they suggest that in all
these cases we have quasi-integrability. Of course, as mentioned arealier on we plan to look at
this further studying the cases of the life-times of these breather-like configurations.

In figure 2 where the breather is short lived we see that the anomaly $\alpha_3$ does not oscillate
within a fixed interval and the integrated anomaly $\beta_3$ does vary a lot. Thus, there is indeed a
correlation between long lived/short lived breathers and well/badly behaved anomalies. The
same is seen, in other similar simulations like, e.g. figure 3. However, the effect of the $\gamma$
parameter is not very visible in the behaviour of the anomalies. It seems that the other effect

Figure 9. Breather’s simulation in the theory (2.1) with initial configuration (3.4),
and with parameters given by $\varepsilon = 0.2$, $\nu = 0.5$ and $\gamma = 0$. The plot shows the time
dependence (adimensional units) of the energy (3.5).

Figure 10. Comparison plots of the time dependence of the energy (3.5) (in adimensional
units) for simulations with $\varepsilon = 0.3$ in the theory (2.1) with initial configuration (3.4).
Plot (a) compares the decrease of the energy for simulations with $\gamma = 0$ and with $\nu = 0.1$
top curve), $\nu = 0.5$ (middle curve) and $\nu = 0.9$ (bottom curve). Plot (b) compares
simulations with $\nu = 0.5$ for $\gamma = 0.2$ (top curve) and $\gamma = 0.0$ (bottom curve).
discussed above in connection with the low initial kinetic energy seems to be predominant in these cases. Of course, the breather of figure 2 also starts moving and when it reflects itself from the boundary its energy drops and the same is true for the anomaly and time integrated anomaly. To save space we have not presented the plot of the time dependence of the field at $x = 0$ in the grid.

![Figure 11. Breather’s simulation in the theory (2.1) with initial configuration (3.4), and with parameters given by of $\varepsilon = 0.3$, $\nu = 0.5$ and $\gamma = 0.5$. The plots show the time dependence of (adimensional units): (a) the energy (3.5); and (b) the field $\phi$ at $x = 0$ in the grid.](image1)

![Figure 12. Breather’s simulation in the theory (2.1) with initial configuration (3.4), and with parameters given by of $\varepsilon = 0.3$, $\nu = 0.5$ and $\gamma = 0.0$. The plots show the time dependence of (adimensional units): (a) time dependence of the field $\phi$ at position $x = 0$ in the grid, at the beginning of the simulation and (b) the same time dependence of the field at a much later time.](image2)

discussed above in connection with the low initial kinetic energy seems to be predominant in these cases. Of course, the breather of figure 2 also starts moving and when it reflects itself from the boundary its energy drops and the same is true for the anomaly and time integrated anomaly. To save space we have not presented the plot of the time dependence of the field at $x = 0$ (but it looks similar to the plot of the field shown in figure 5).

We have also observed that the energy of the breather-like solutions, after they have stabilized, seems to depend on the frequency in a way very similar to the exact sine-Gordon
breather, i.e. \( E \sim \sqrt{1 - \nu^2} \). In figure 12 we show, for the case of \( \epsilon = 0.3, \nu = 0.5 \) and \( \gamma = 0.0 \), the time dependence of the field \( \phi \) at \( x = 0 \), in the left figure at the beginning of the simulation and in the right figure the same time dependence of the field at a much later time. From these two plots it is very clear that at first the breather oscillates with a period of \( T \sim 6.8 \) and much much later this period has decreased to \( T \sim 6.62 \). Thus the frequency of this quasi-breather has increased from \( \nu \sim 0.92 \) to \( \nu \sim 0.95 \). Initially the energy was \( E_{\text{in}} = 1.749 \) and at the end \( E_{\text{fin}} = 1.409 \). Thus the reduction of energy was roughly \( \frac{1.749}{1.409} \sim 1.24 \) which is quite small.

Note that for genuine breathers of the sine-Gordon model the energy is proportional to \( E \sim \sqrt{1 - \nu^2} \), so let us check what would have happened had we used this fact to estimate the energies in this case too (as our field configuration resembles the sine-Gordon model’s breather so well). We would have had

\[
\left( \frac{E_{\text{in}}}{E_{\text{fin}}} \right)^2 = \frac{1 - \nu_{\text{in}}^2}{1 - \nu_{\text{fin}}^2},
\]

(3.10)

In our case the left and right hand sides of this formula are given by

\[
(1.24)^2 \sim 1.54, \quad \frac{1 - (0.92)^2}{1 - (0.95)^2} \sim 1.57
\]

(3.11)

thus showing that this approximation is good to within \( \sim 3\% \).

We have also looked at the energy drop in simulations involving small \( \epsilon \). In such cases we had the initial drop of the energy (like for larger values of \( \epsilon \)) followed by a motion of the breather towards the boundaries with a reflection of it from the boundaries (producing a further sharp drop of the energy at each reflection). This is clear from the simulation shown in figure 4 (see figure (a)). The observed movement of the breather is somewhat unexpected and it seems to have taken place primarily for ‘short-lived’ breathers. The motion of the breather probably is generated by numerical perturbations of large fields (as the amplitude of their field becomes different from the amplitude of the corresponding Sine-Gordon field). It would be interesting to check whether some of our breather-like structures never move but given the time of the simulations required for such studies this is not really a practical proposition.

Given the irregularity of the energy drop of the moving breathers it makes little sense to perform a comparison of the energy loss to the increase of the frequency of the oscillation that we have performed for larger values of \( \epsilon \). So if we want to perform a similar calculation we have to restrict our attention to the initial (non-moving) times of the breather, (i.e. consider it only for \( t \) up to \( \sim 48000 \)). Hence, in figure 4 we present the plot of the previous figure for the range of \( t \) up to this value. This we also have to do with the variation of the field at \( x = 0 \) so in the last two figures of figure 4, namely (c) and (d) we present the variation of the field at the beginning of this interval and at the end of it. The plots cover the range of \( t \) of 200 units and they show that at the beginning of the simulation the system performed \( \sim 18.5 \) oscillations in 200 units of time, while at \( t \sim 47900 \) this has increased to about 21.2.

This shows that the frequency of the breather has increased from 0.58 to about 0.66. During the same time the energy has changed from about 6.31 to 5.79.

The square of the ratio of energies is thus given by \( \left( \frac{6.31}{5.79} \right)^2 \sim 1.188 \) and this is in a quite good agreement with the ratio...
\[
\frac{1 - (0.58)^2}{1 - (0.66)^2} \sim 1.176.
\]  
\(3.12\)

Hence again we have results in a good agreement with our expectations.

In figures 5 and 6, on the left hand side, we present plots of the time dependence of the energy for \(\varepsilon = 0.01\) but this time for larger values of \(\gamma\); namely \(\gamma = 0.2\) (5) and \(\gamma = 0.5\) (6). The results are not that different from what we saw for \(\gamma = 0\) except that the decrease of energy is progressively greater. In fact, in each case, the energy start decreasing quite fast but then the decrease slows down. Again, the breathers start moving and so, again, we could calculate the increase of frequencies of oscillations and, like before, compare our expressions with the decrease of energies but only before they have moved. To assess the time at which the breathers have started moving we look at second plots in figures 5 and 6 in which we plot the time dependence of the field at \(x = 0\). As soon as the breathers have started moving the amplitude of the field at \(x = 0\) begins to decrease as the breather is not localised around \(x = 0\). So, for the case described in figure 5, the final value of \(t\) is about \(t \sim \times 4.9 \times 10^4\) and by then the energy has significantly decreased.

Looking at the files in detail we find that in the case of \(\gamma = 0.2\) the respective energies are approximately 6.38 and 5.09. Hence

\[
\left(\frac{6.38}{5.09}\right)^2 \sim 1.57.
\]  
\(3.13\)

The frequencies are approximately \(\nu_i = 0.58\) and \(\nu_f = 0.75\), respectively and so we get

\[
\frac{1 - \nu_i^2}{1 - \nu_f^2} \sim 1.52
\]  
\(3.14\)

showing that, again, both sets of numbers are quite close together.

For \(\gamma = 0.5\) (figure 6) the corresponding energies are approximately 6.49 and 4.50. The frequencies are approximately \(\nu_i = 0.60\) and \(\nu_f = 0.82\). Thus, as before, we get

\[
\left(\frac{6.49}{4.50}\right)^2 \sim 2.08
\]  
\(3.15\)

and

\[
\frac{1 - \nu_i^2}{1 - \nu_f^2} \sim 1.95
\]  
\(3.16\)

in a quite good agreement with the corresponding ratio from the energies.

Let us add here that all our calculations are not very precise as they involved calculating the energy at regular intervals and also estimating the frequency of the breather-like structure by looking at the number of oscillations over a suitably long period of time. However, we were constrained by two effects, the changing nature of the oscillations and the occasional movement of the breathers. This was the case for ‘long-lived’ breathers which lost their energy extremely slowly; hence, occasionally, they were perturbed by some small random perturbations hence, given the way collected our data, we had to wait for the breather to return to the region where we could trust our results. Thus all the data mentioned above have small errors associated with these effects. We have tried to assess these errors and the numbers above are given with \(\sim\) sign to emphasise this uncertainty. However, our numerical work has shown us that our understanding understanding of what is going on is sensible and that the symmetry
plays an important role in lengthening the life-time of our breather-like structures. Thus we will try to look at such systems in more detail using the techniques of Fordor at al [15].

4. Further comments and some conclusions

In this paper we have discussed results of our more detailed studies of quasi-integrability based on the observation in [2, 3] about the behaviour of the anomaly $X$ of the curvature (2.15) of the Lax potentials, which distinguishes integrable models from non-integrable ones. We have found that the anomaly integrated in time (see for instance (3.9)) also vanishes in some non-integrable models for field configurations which possess the parity symmetries discussed in section 2.

This observation was originally made in some very specific models and here we have tried to assess its general validity. So, in [4] we constructed three classes of models (one with symmetry, one without it and one (dependent on two parameters)) which would allow us to interpolate between the two. Our results have confirmed the validity of our assumption (and so extended the class of models in which our observation holds) and have also allowed us to study the way the anomaly varies as we move away from the models with this extra symmetry. These results were first tested in great detail for the scattering of kinks of these models. Of course, in such scatterings the kinks interact with each other only over very short periods of time (when they were close to each other). So we have decided to look also at the systems involving breather-like structures in which the kinks and anti-kinks, being bound into breathers, interact with each other all the times. In our previous work [4] we have only glanced at such configurations and have presented only very preliminary results. As the breather-like configurations depend on many parameters, in this paper we have concentrated our attention at looking at them in detail, in particular, looking at the difference in the breathers’ behaviour depending on whether the symmetry is present or not. As expected, we have found that the symmetry helps a lot in the validity of ideas of quasi-integrability. When the symmetry is present the energy decrease is much reduced and the configurations resemble, in their behaviour, the sine-Gordon breathers. When the symmetry is broken the breathers decay quite rapidly and the range of validity of quasi-integrability is much reduced.

However, the symmetry is only one of many topics to investigate for the breather-like configurations. We have also looked at the way the decay takes place and the dependence of this behaviour on various parameters of the model. One of the most interesting outcomes of our simulations is the understanding of the way the decay takes place. The breathers increase the frequency of their oscillations. This is quite clear from the energy of our initial configuration (3.6) but it is amazing to observe that as the breather-like field looses its energy this formula still holds, as only the parameter $\nu$ in it increases. In our simulations some breather-like configurations started moving and lost their energies also by reflecting from the edges of the grid. For them the frequency increased even more so that their total energy (consisting of the energy of the oscillation and the energy of the motion was comparable to the final energy of the field, and much lower than the original energy).

Furthermore, our work has lead to the discovery of the existence of many long lived breather-like fields a long way away (i.e. for large perturbations) from the sine-Gordon model. This was particularly true for the cases with symmetry and so it is clear that the symmetry does extend the range of validity of quasi-integrability.

The main parts of our work were numerical. By this it complements the analytical work mentioned in the Introduction. The small amounts of analytical work on similar problems only involved power series expansions and all results we are familiar with were only valid to
first order in the parameters of these expansions. Our numerical results are nonperturbative but, as is the case with all numerical work, our work also had some numerical errors which we tried to minimise and, having experimented with different lattice spacings and different numerical approaches we are confident that our results are reliable. Of course the hope is that our results will encourage some analysts to return to these problems and try to say something more definitive about our breather-like configurations and, by doing so, help us to place our ideas on quasi-integrability on much more solid footing.

Acknowledgments

The work reported in this paper was started when the authors were ‘researching in pairs’ at the Matematisches Forschunginstitute in Oberwolfach. They would like to thank the Oberwolfach Institute for its hospitality. The work was finished when WJZ was visiting the São Carlos Institute of Physics of the University of São Paulo (IFSC/USP). His visit was supported by a grant from FAPESP. He would like to thank FAPESP for this grant and the IFSC/USP for its hospitality. LAF’s work was partially supported by CNPq (Brazil).
