Abstract. The smallest positive eigenvalue of the Laplacian of a network is called the spectral gap and characterizes various dynamics on networks. We propose mathematical programming methods to maximize the spectral gap of a given network by removing a fixed number of nodes. We formulate relaxed versions of the original problem using semidefinite programming and apply them to example networks.

Keywords: combinatorial optimization; network; synchronization; random walk; opinion formation; Laplacian; eigenvalue

1 Introduction

An undirected and unweighted network (i.e., graph) on $N$ nodes is equivalent to an $N \times N$ symmetric adjacency matrix $A = (A_{ij})$, where $A_{ij} = 1$ when nodes (also called vertices) $i$ and $j$ form a link (also called edge), and $A_{ij} = 0$ otherwise. We define the Laplacian matrix of the network by

$$L \equiv D - A,$$ (1)

where $D$ is the $N \times N$ diagonal matrix in which the $i$th diagonal element is equal to $\sum_{j=1}^{N} A_{ij}$, i.e., the degree of node $i$.

When the network is connected, the eigenvalues of $L$ satisfy

$$\lambda_1 = 0 < \lambda_2 \leq \cdots \leq \lambda_N.$$ (2)

The eigenvalue $\lambda_2$ is called spectral gap or algebraic connectivity and characterizes various dynamics on networks including synchronizability [3,4,10], speed of synchronization [3], consensus dynamics [17], the speed of convergence of the Markov chain to the stationary density [8,10], and the first-passage time of the
random walk \cite{10}. Because a large $\lambda_2$ is often considered to be desirable, e.g., for strong synchrony and high speed of convergence, maximization of $\lambda_2$ by changing networks under certain constraints is important in applications.

In the present work, we consider the problem of maximizing the spectral gap by removing a specified number, $N_{\text{del}}$, of nodes from a given network. We assume that an appropriate choice of $N_{\text{del}}$ nodes keeps the network connected. A heuristic algorithm for this task in which nodes are sequentially removed is proposed in \cite{20}. In this study, we explore a mathematical programming approach. We propose two algorithms using semidefinite programming and numerically compare their performance with that of the sequential algorithm proposed in \cite{20}.

2 Methods

We start by introducing notations. First, the binary variable $x_i$ ($1 \leq i \leq N$) takes a value of 0 if node $i$ is one of the $N_{\text{del}}$ removed nodes and 1 if node $i$ survives the removal. Our goal is to determine $x_i$ ($1 \leq i \leq N$) that maximizes $\lambda_2$ under the constraint

$$\sum_{i=1}^{N} x_i = N - N_{\text{del}}. \quad (3)$$

Second, we define $\tilde{L}_{ij}$ as the $N \times N$ Laplacian matrix generated by a single link $(i, j) \in E$, where $E$ is the set of links. In other words, the $(i, j)$ and $(j, i)$ elements of $\tilde{L}_{ij}$ are equal to 1, the $(i, j)$ and $(j, i)$ elements of $\tilde{L}_{ij}$ are equal to $-1$, and all the other elements of $\tilde{L}_{ij}$ are equal to 0. It should be noted that

$$L = \sum_{1 \leq i < j \leq N, (i, j) \in E} \tilde{L}_{ij}. \quad (4)$$

Third, $J$ denotes the $N \times N$ matrix in which all the $N^2$ elements are equal to unity. Fourth, $E_i$ denotes the $N \times N$ diagonal matrix in which the $(i, i)$ element is equal to unity and all the other $N^2 - 1$ elements are equal to 0.

After the removal of $N_{\text{del}}$ nodes, we do not decrease the size of the Laplacian. Instead, we remove $\tilde{L}_{ij}$ from the summation on the RHS of Eq. (3) if node $i$ or $j$ has been removed from the network. The Laplacian of the remaining network, if connected, has $N_{\text{del}} + 1$ zero eigenvalues. The corresponding zero eigenvectors are given by $u^{(0)} \equiv (1 \cdots 1)^T$ and $e_i$, where $^T$ denotes the transposition, $e_i$ is the unit column vector in which the $i$th element is equal to 1 and the other $N-1$ elements are equal to 0, and $i$ is the index of one of the $N_{\text{del}}$ removed nodes.

We formulate a nonlinear eigenvalue optimization problem, which we call EIGEN, as follows:

$$\text{maximize } t \quad \text{subject to Eq. (3) and}$$

$$-tI + \sum_{i < j; (i, j) \in E} x_i x_j \tilde{L}_{ij} + \alpha J + \beta \sum_{i=1}^{N} (1 - x_i) E_i \succeq 0, \quad (5)$$
and \( x_i \in \{0, 1\} \) (\( 1 \leq i \leq N \)), where \( \succeq 0 \) indicates that the LHS is a positive semidefinite matrix. The positive semidefinite constraint Eq. (5) is derived from a standard prescription in semidefinite programming for optimization of an extreme eigenvalue of a matrix. Maximizing \( t \) is equivalent to maximizing the smallest eigenvalue of the matrix given by the sum of the second, third, and fourth terms on the LHS of Eq. (5).

Without the third and fourth terms on the LHS of Eq. (5), the optimal solution would be trivially equal to \( t = 0 \) because the Laplacian of any network has 0 as the smallest eigenvalue. Because \( J = u^{(0)}u^{(0)\top} \), the third term transports a zero eigenvalue to \( \approx \alpha \). We should take a sufficiently large \( \alpha > 0 \) such that the zero eigenvalue is shifted to a value larger than the spectral gap of the remaining network, denoted by \( \tilde{\lambda}_2 \). This technique was introduced in [9] for solving the traveling salesman problem.

For each removed node \( i \) (i.e., \( x_i = 0 \)), the matrix represented by the second term on the LHS of Eq. (5) has a zero eigenvalue associated with eigenvector \( e_i \). The fourth term shifts this zero eigenvalue to \( \approx \beta \). Note that the fourth term disappears for the remaining \( N - N_{\text{del}} \) nodes because \( x_i = 1 \) for the remaining nodes. If the shifted eigenvalues are larger than \( \tilde{\lambda}_2 \), the solution to the problem stated above returns the \( N_{\text{del}} \) nodes whose removal maximizes \( \tilde{\lambda}_2 \).

The second term on the LHS of Eq. (5) represents a nonlinear constraint. To linearize the problem in terms of the variables, we follow a conventional prescription to introduce auxiliary variables

\[
X_{ij} \equiv x_ix_j, \quad (1 \leq i < j \leq N) \tag{6}
\]

where \( 1 \leq i \leq N \) (also reviewed in [12]). If \( x_i \) is discrete, \( x_i(1-x_i) = 0 \) holds true. Therefore, we require \( X_{ii} = x_i^2 = x_i \). In the following discussion, we use \( x_i \) in place of \( X_{ii} \).

We define the \( (N+1) \times (N+1) \) matrix

\[
Y \equiv \begin{bmatrix} 1 & \mathbf{x}^\top \\ \mathbf{x} & X \end{bmatrix}, \quad (7)
\]

where \( \mathbf{x} \equiv (x_1 \ldots x_N)^\top \), the \((i,i)\) element of the \( N \times N \) matrix \( X \) is equal to \( x_i \), and the \((i,j)\) element \((i \neq j)\) of \( X \) is equal to \( X_{ij} \). By allowing \( x_i \) and \( X_{ij} \) \((1 \leq i, j \leq N)\) to take any continuous value between 0 and 1, we define the relaxed problem named SDP1 as follows:

\[
\text{maximize } t \quad \text{subject to Eq. (3) and}
\]

\[
-tI + \sum_{i<j; (i,j) \in E} X_{ij} \tilde{L}_{ij} + \alpha J + \beta \sum_{i=1}^{N} (1-x_i)E_i \succeq 0, \quad (8)
\]

\[
Y \succeq 0. \quad (9)
\]

Note that Eq. (9) implies \( 0 \leq x_i \leq 1 \) \((1 \leq i \leq N)\) and that SDP1 relaxes the original problem in that \( x_i \) and \( X_{ij} \) are allowed to take continuous values.
while Eq. (9) is imposed. The method that we propose here for approximately maximizing the spectral gap is to remove the \( N_{\text{del}} \) nodes corresponding to the \( N_{\text{del}} \) smallest values among \( x_1, \ldots, x_N \) in the optimal solution of SDP1.

SDP1 involves \( N(N+1)/2 + 1 \) variables (i.e., \( t, x_i, \) and \( X_{ij} \) with \( i < j \)). In fact, \( X_{ij} \) for \( (i, j) \notin E \) is free unless Eq. (9) is violated; it does not appear in the main positive semidefinite constraint represented by Eq. (8). Because a given network is typically sparse, this implies that there are many redundant variables in SDP1. To exploit the sparsity and thus to save time and memory space, a technique based on matrix completion might be useful [11, 16]. In this paper, however, we propose another relaxation SDP2 for this purpose.

To linearize the second term on the LHS of Eq. (5), we take advantage of four inequalities

\[
    x_i x_j \geq 0, \quad x_i (1 - x_j) \geq 0, \quad (1 - x_i) x_j \geq 0, \quad (1 - x_i)(1 - x_j) \geq 0
\]

that must be satisfied for any link \((i, j) \in E\). By defining \( X_{ij} \equiv x_i x_j \), as in the case of SDP1, we obtain the following four linear constraints [18]:

\[
    X_{ij} \geq 0, \quad x_i - X_{ij} \geq 0, \quad x_j - X_{ij} \geq 0, \quad 1 - x_i - x_j + X_{ij} \geq 0.
\]

SDP2 is defined by replacing Eq. (9) by Eqs. (10)–(13), where only the pairs \((i, j) \in E\) are considered. Note that Eqs. (10)–(13) guarantee \( 0 \leq x_i \leq 1 \) (\( 1 \leq i \leq N \)). We remove the \( N_{\text{del}} \) nodes corresponding to the \( N_{\text{del}} \) smallest values among \( x_1, \ldots, x_N \) in the optimal solution of SDP2.

Numerically, SDP2 is much easier to solve than SDP1 for two reasons. First, the number of variables is smaller in SDP2 than in SDP1. In SDP2, \( X_{ij} \) is defined only on the links, whereas in SDP1 it is defined for all the pairs \( 1 \leq i < j \leq N \). In sparse networks, the number of variables is \( O(N^2) \) for SDP1 and \( O(N) \) for SDP2. Second, the positive semidefinite constraint, which is much more time consuming to solve than a linear constraint of a comparable size, is smaller in SDP2 than in SDP1. While SDP1 and SDP2 share the \( N \times N \) positive semidefinite constraint (8), SDP1 involves an additional positive semidefinite constraint (9) of size (\( N + 1 \)) \times (\( N + 1 \)).

To determine the values of \( \alpha \) and \( \beta \), we consider the matrix represented by the sum of the second, third, and fourth terms on the LHS of Eq. (5). A straightforward calculation shows that the eigenvalues of this matrix are given by the \( N - N_{\text{del}} - 1 \) positive eigenvalues of the Laplacian of the remaining network, \((N_{\text{del}} - 1)\)-fold \( \beta \), and \( \beta + \left[ \alpha N - \beta \pm \sqrt{(\alpha N - \beta)^2 + 4N_{\text{del}}\alpha\beta} \right]/2 \). For a fixed \( \beta \), we should select \( \alpha \) to maximize \( \beta + \left[ \alpha N - \beta - \sqrt{(\alpha N - \beta)^2 + 4N_{\text{del}}\alpha\beta} \right]/2 \), which is always smaller than eigenvalue \( \beta \). We set

\[
    \alpha = \frac{\beta}{N}
\]

to simplify the expression of this eigenvalue to \( \beta(1 - \sqrt{N_{\text{del}}/N}) \) while approximately maximizing this eigenvalue.
We have the following bounds for the optimal solution to the original problem. We denote by $\tilde{\lambda}_{\text{opt}}^2$ the optimal solution, i.e., the maximum spectral gap with $N_{\text{del}}$ nodes removed. We denote by $\tilde{\lambda}_{\text{SDP}}^2$ the smallest positive eigenvalue of the network obtained by the proposed method; the proposed method removes the $N_{\text{del}}$ nodes corresponding to the $N_{\text{del}}$ smallest values of $x_1, \ldots, x_N$ in the optimal solution of SDP1 or SDP2. Obviously, $\tilde{\lambda}_{\text{SDP}}^2$ is a lower bound for $\tilde{\lambda}_{\text{opt}}^2$. On the other hand, the optimal value, $\max t$, of SDP1 or SDP2 serves as an upper bound for $\tilde{\lambda}_{\text{opt}}^2$, as long as the $\beta$ satisfies $\tilde{\lambda}_{\text{opt}}^2 \leq \beta(1 - \sqrt{N_{\text{del}}/N})$. This follows from the facts that the optimal value of EIGEN with such a $\beta$ value coincides with $\tilde{\lambda}_{\text{opt}}^2$ and both SDP1 and SDP2 are a relaxation of EIGEN. We can summarize our observation as follows: $\tilde{\lambda}_{\text{SDP}}^2 \leq \tilde{\lambda}_{\text{opt}}^2 \leq \max t$.

3 Numerical results

In this section, we apply SDP1 and SDP2 to some synthetic and real networks. We implement SDP1 and SDP2 using the free software package SeDuMi 1.3 that runs on MATLAB 7.7.0.471 (R2008b) [1].

We compare the performance of SDP1 and SDP2 with that of the optimal sequential method, which is a heuristic method proposed in [20]. In the optimal sequential method, we numerically calculate the spectral gap for the network obtained by the removal of one node; we do this for all possible choices of a node to be removed. Subsequently, we remove the node whose removal yields the largest spectral gap. Then, for the remaining network composed of $N - 1$ nodes, we determine the second node to be removed in the same way. We repeat this procedure until $N_{\text{del}}$ nodes have been removed.

The first example network is the well-known karate club social network, in which a node represents a member of the club and a link represents casual interaction between two members [21]. The network has $N = 34$ nodes and 78 links. We set $\beta = 2$. The spectral gaps obtained by the different node removal methods are shown in Fig. 1(a) as a function of $N_{\text{del}}$. Up to $N_{\text{del}} = 5$, the optimal sequential method yields the exact solution, as do SDP1 and SDP2. For $N_{\text{del}} \geq 6$, we could not obtain the exact solution by the exhaustive search because of the combinatorial explosion. For $7 \leq N_{\text{del}} \leq 16$, SDP1 and SDP2 perform worse than the optimal sequential method. However, for $N_{\text{del}} \geq 17$, both SDP1 and SDP2 outperform the optimal sequential method. SDP1 and SDP2 found efficient combinations of removed nodes that the optimal sequential method could not find.

Second, we test the three methods against the largest connected component of the undirected and unweighted version of a macaque cortical network [19]. The network has $N = 71$ nodes and 438 links. We set $\beta = 2$. The spectral gaps obtained by the different methods are shown in Fig. 1(b). Up to $N_{\text{del}} = 4$, the optimal sequential method yields the exact solution, as do SDP1 and SDP2. For $N_{\text{del}} \geq 5$, we could not obtain the exact solution because of the combinatorial explosion. For $N_{\text{del}} \geq 5$, SDP1 and SDP2 perform worse than the optimal sequential method. Consistent with the poor performance of SDP1
and SDP2, the final values of $x_i$ (1 ≤ i ≤ N) are not bimodally distributed around 0 and 1 as SDP1 and SDP2 implicitly suppose. The distribution is rather unimodal except for the first three values of $x_i$ that are close to 0. The ten values of $x_i$ when $N_{\text{del}} = 5$, in ascending order, are as follows: $x_{33} = 0.1086$, $x_{62} = 0.1531$, $x_{53} = 0.1589$, $x_1 = 0.4813$, $x_2 = 0.5246$, $x_8 = 0.5591$, $x_7 = 0.6449$, $x_{24} = 0.7866$, $x_{51} = 0.8749$, and $x_{63} = 0.8931$ in SDP1, and $x_{53} = 0.000$, $x_{33} = 0.145$, $x_{62} = 0.177$, $x_2 = 0.585$, $x_1 = 0.588$, $x_8 = 0.610$, $x_7 = 0.668$, $x_{24} = 0.708$, $x_5 = 0.738$, and $x_4 = 0.937$ in SDP2.

Fig. 1. Spectral gap as a function of the number of removed nodes for four networks. (a) Karate club social network with $N = 34$ nodes. (b) Macaque cortical network with $N = 71$ nodes. (c) Barabási–Albert scale-free network with $N = 150$ nodes. (d) C. elegans neural network with $N = 279$ nodes.

The third network is a network with $N = 150$ nodes generated by the Barabási–Albert scale-free network model [5]. The growth of the network starts with a connected pair of nodes, and each incoming node is assumed to have two links. The generated network has 297 links. We set $\beta = 2$. For this and the next networks, SDP1 cannot be applied because $N$ is too large. Therefore, we only compare the performance of SDP2 against the optimal sequential method. The results shown in Fig. 1(c) indicate that SDP2 outperforms the optimal sequential method when $N_{\text{del}} \geq 7$. 
The fourth network is the largest connected component of the C. elegans neural network [2, 7]. Two nodes are regarded as being connected when they are connected by a chemical synapse or gap junction. We ignore the direction and weight of links. The network has $N = 279$ nodes and $2287$ links. We set $\beta = 2.5$. The results for SDP2 and the optimal sequential method are shown in Fig. 1(d). Although the spectral gap gradually increases with $N_{\text{del}}$ for SDP2, SDP2 performs poorly as compared to the optimal sequential method for this example.

4 Discussion

We proposed a method to maximize the spectral gap using semidefinite programming. The two proposed algorithms have a firmer mathematical foundation as compared to the heuristic numerical method (i.e., optimal sequential method). The proposed algorithms performed better than the heuristic method for two networks especially for large $N_{\text{del}}$ and worse for the other two networks. For the former two networks, we could find the solutions in the situations in which the exhaustive search is computationally formidable. Up to our numerical efforts, our algorithms seem to be efficient for sparse networks.

We should be careful about the choice of $\beta$. If $\beta$ is too large, SDP1 and SDP2 would result in $x_i \approx N_{\text{del}}/N$ ($1 \leq i \leq N$). This is because setting $x_i = N_{\text{del}}/N$ ($1 \leq i \leq N$) makes the fourth term on the LHS of Eq. (5) equal to $\beta N_{\text{del}} - N_{\text{del}}/N$, which increases all the eigenvalues, including the spectral gap of the remaining network, by $\beta N_{\text{del}} - N_{\text{del}}/N$. In contrast, if $\beta$ is smaller than $\tilde{\lambda}_2$, SDP1 and SDP2 would maximize a false eigenvalue originating from the fourth term on the LHS of Eq. (5).

To enhance the performance of SDP1 and SDP2, it may be useful to abandon the convexity of the problem. For example, we could try replacing $(1 - x_i)$ in the fourth term by $(1 - x_i)^p$ and gradually increase $p$ from unity. When $p > 1$, the problem is no longer convex. Accordingly, the existence of the unique solution and the convergence of a proposed algorithm are not guaranteed. Nevertheless, we may be able to track the optimal solution $\mathbf{x}$ by the Newton method while we gradually increase $p$ (see p.5 and p.63 in [6]). An alternative extension is to add $-p \sum_{i=1}^{N} x_i (1 - x_i)$ to the objective function to be maximized (i.e., $t$). When $p > 0$, the convexity is violated. However, we may be able to adopt a procedure similar to the method explained above, i.e., start with $p = 0$ and gradually increase $p$ to track the solution by the Newton method.
