Fractional networks, the new structure

Abstract
Real world networks have, for a long time, been modelled by scale-free networks, which have many sparsely connected nodes and a few highly connected ones (the hubs). However, both in society and in biology, a new structure must be acknowledged, the fractional networks. These networks are characterized by the existence of very many long-range connections, display superdiffusion, Lévy flights and robustness properties different from the scale-free networks.

1 Introduction
The scale-free network [1] has been for some time the preferred paradigm for modeling real world networks in society, biology, etc. Characterized by asymptotic power-law degree distribution, these networks have many sparsely connected nodes and a few highly connected ones (the hubs). The hubs are the critical nodes to address (or protect) in a network, because they control the robustness of the network and the diffusion of information. This is a fact well known by politicians, advertisement agencies and hackers. The importance of hubs has been known for a long time, even at the time of the Inquisition [2]. Several mechanisms, preferential attachment or fitness for example, have been proposed to explain the formation of this network structure. Many networks have been reported to be scale-free although careful statistical analysis has questioned others [3].

A feature that has recently emerged in some social networks (see for example [4] [5] [6]) is the existence of very many long-range connections, rather than hubs. In a sense society imitates Nature because also brain network phenomena, for example, have been shown to be dependent on many long-range connections [7] [8] [9] [10]. Also the human mobility network has long range connections of great relevance in epidemiology [11]. It is to be expected that the existence of a sufficient number of long range connections in a network would lead to new phenomena and have a strong effect on the propagation of information.

Some authors have already studied dynamics on networks involving jumps over many links leading to fractional diffusion [12]. What one wants to emphasize here is that fractional diffusion and other phenomena emerge naturally as a structural property in networks with long range connections. Hence these networks should be classified as a new structure.

2 Long-range connections: Lévy flights and superdiffusion

2.1 The Laplacian and Random Walk matrices

The Laplacian and the Random Walk matrices are the main tools in the study of dynamical properties in the network. The Laplacian matrix is

$$ L = G - A $$

\( G \) being the degree matrix \((G_{ij} = \delta_{ij} \times \text{number of connections of node } i)\) and \( A \) the adjacency matrix \((A_{ij} = 1 \text{ if } i \text{ and } j \text{ are connected, } A_{ij} = 0 \text{ otherwise})\).

The Random-Walk matrix is

$$ R = G^{-1}A $$

then, \( R_{ii} = 0 \), \( R_{ij} = \frac{A_{ij}}{\text{degree}(i)} \) (\( i \neq j \)) if \( i \) and \( j \) are connected and \( R_{ij} = 0 \) otherwise.

For a node \( i \) connected to two other nodes \( i + 1 \) and \( i - 1 \) the action of the Laplacian matrix on a vector

$$ \begin{bmatrix} \vdots \\ \psi(i-1) \\ \psi(i) \\ \psi(i+1) \\ \vdots \end{bmatrix} $$

leads to \(-\psi(i-1) + 2\psi(i) - \psi(i+1)\), which is a discrete version of \(-d^2\) (minus the second derivative). Let now \( \psi(i) \) for each node \( i \) be the intensity of some function \( \psi \) across the network. It is reasonable to think that \( \psi \) diffuses from \( i \) to \( j \) proportional to \( \psi(i) - \psi(j) \) if \( i \) and \( j \) are connected. Then,

$$ \frac{d\psi(i)}{dt} = -k \sum_j A_{ij} (\psi(i) - \psi(j)) = -k \left( \psi(i) \sum_j A_{ij} - \sum_j A_{ij} \psi(j) \right) $$

which in matrix form is

$$ \frac{d\psi}{dt} + kL\psi = 0 $$

a heat-like equation. Therefore the Laplacian matrix controls the diffusion of quantities in the network.
On the other hand, the $R$ matrix controls the random motion of a walker on the network. The probability for a random walker to be at the node $i$ at time $t$ given that at time $t-1$ was at the node $j$ is

$$p_i(t) = \sum_j \frac{A_{ij}}{\text{degree}(j)} p_j(t-1)$$

(5)

or, in matrix form

$$p(t) = G^{-1} A p(t-1)$$

(6)

### 2.2 A network with power-law connection probability

Let the network $N$ be embedded into an Euclidean network where distances may be defined. In the actual network the distances might mean geographical distances, separation of communities, functional separation as in a brain network, etc.

In the network, with $A_{ij} = 0$ or 1, let the probability of establishment of a link at distance $d$ be proportional to a power of the distance

$$P_{ij} = cd_i^{-\gamma}$$

with $\gamma \leq 3$

(7)

To find the nature of the diffusion in such a network, consider a block renormalized network $N^*$ where each set of $q$ nearby nodes of $N$ are mapped to a node of the $N^*$ network. Therefore in the $N^*$ network the connections are

$$A_{ij}^* \simeq cq d_i^{-\gamma}$$

(8)

Then denoting by $L^*$ and $G^*$ the Laplacian and degree matrices of the $N^*$ network

$$L^* \psi(i) = G^* \psi(i) - cq \sum_{j \neq i} d_{ij}^{-\gamma} \psi(j)$$

(9)

What kind of diffusion does the Laplacian matrix $L^* = G^* - A^*$ imply for the network $N^*$? Consider a fractional diffusion equation

$$\frac{d\psi}{dt} = -kD^{\beta}\psi$$

(10)

Using a symmetrized Grünwald-Letnikov representation of the fractional derivative ($a < x < b$) (see for example [13])

$$D^{\beta}\psi(x) = \frac{1}{2} \lim_{h \to 0} \frac{1}{h} \left\{ \sum_{n=0}^{[\frac{x-a}{h}]} (-1)^n \binom{\beta}{n} \psi(x-nh) + \sum_{n=0}^{[\frac{b-x}{h}]} (-1)^n \binom{\beta}{n} \psi(x+nh) \right\}$$

(11)
with coefficients
\[
\begin{align*}
&\left( \beta \atop n \right) = \frac{\Gamma (\beta + 1) |\sin (\pi \beta)| \Gamma (n - \beta)}{\pi \Gamma (n + 1)} \sim_\gamma > \frac{\Gamma (\beta + 1) |\sin (\pi \beta)|}{\pi} n^{-(\beta+1)}
\end{align*}
\]

and \( \text{sign} \left( \frac{\beta}{n} \right) = (-1)^{n+1} \).

Comparing Eq. (11) with the expression (9) for \( L^* \psi (i) \), the conclusion is that diffusion in the \( N^* \) network is fractional diffusion of exponent \( \beta = \gamma - 1 \). \( \beta = 2 \) would be normal diffusion, all \( \beta < 2 \) correspond to superdiffusions. That is, the spreading in time \( \langle x^2 (t) \rangle \) of a distribution localized at \( x = 0 \) at \( t = 0 \) is
\[
\langle x^2 (t) \rangle \sim t^{2\gamma}
\]

On the other hand, analyzing the structure of the random walks controlled by \( G^{-1} A \) (Eq.6) the conclusion is that whereas for normal diffusion the jumps are of one step, for \( \gamma < 3 \) arbitrarily large large jumps occur with a power law (Lévy flights).

3 Conclusions

1. The first general conclusion is that in these networks both mobility and diffusion of information occur at a very fast rate. Therefore it may considered as a new structure distinct from SF networks, a Fractional Network (FR). The new structure has wide implications for the control of the networks.

2. In a SF network, the hubs are both the strength and the weakness of the network. They insure global connectivity even if a large number of links are destroyed. But when directly targeted the network is deeply affected (targeted structural weakness). In a SF network propagation of ideas, opinions, fads (memes) are most effective if introduced to the hubs. However fast global establishment of a trend requires its introduction at many hubs.

3. A FR network is structurally very stable and resilient to attack. It is pointless or too expensive to disrupt the network. The hubs are no longer the controllers. The network itself is the HUB. Superdiffusion is both the strength and the weakness of the network. Well crafted memes propagate very fast. But also do counter-memes. In SF networks the memes are most efficiently introduced at the hubs. Here they might be introduced anywhere.
