ABSTRACT

We investigate the weak lensing signature of primordial non-Gaussianities of the local type by constraining the magnitude of the weak convergence bi- and trispectra expected for the EUCLID weak lensing survey. Starting from expressions for the weak convergence spectra, bispectra and trispectra, whose relative magnitudes we investigate as a function of scale, we compute their respective signal to noise ratios by relating the polynomials’ amplitude to their Gaussian covariance using a Monte-Carlo technique for carrying out the configuration space integrations. In computing the Fisher-matrix on the non-Gaussianity parameters \( f_{NL} \), \( g_{NL} \) and \( \tau_{NL} \), with a very similar technique, we can derive Bayesian evidences for a violation of the Suyama-Yamaguchi relation \( \tau_{NL} \geq (6f_{NL}/5)^2 \) as a function of the true \( f_{NL} \) and \( \tau_{NL} \)-values and show that the relation can be probed down to levels of \( f_{NL} \approx 10^2 \) and \( \tau_{NL} \approx 10^5 \). In a related study, we derive analytical expressions for the probability density that the SY-relation is exactly fulfilled, as required by models in which any one field generates the perturbations. We conclude with an outlook on the levels of non-Gaussianity that can be probed with tomographic lensing surveys.

Key words: cosmology: large-scale structure, gravitational lensing, methods: analytical

1 INTRODUCTION

Advances in observational cosmology has made it possible to probe models of the early Universe and the mechanisms that can generate small seed perturbations in the density field from which the cosmic large-scale structure grew by gravitational instability. One of the most prominent of these models is inflation, in which the Universe underwent an extremely rapid exponential expansion and where small fluctuations in the inflationary field gave rise to fluctuations in the gravitational potential and which then imprinted these fluctuations onto all cosmic fluids (for reviews, see Bartolo et al. 2004; Seery et al. 2007; Komatsu et al. 2009; Komatsu 2010; Desjacques & Seljak 2010b; Verde 2010; Jeong et al. 2011a; Wang 2013; Martin et al. 2013; Lesgourgues 2013). Observationally, inflationary models can be distinguished by the spectral index \( n_s \) along with a possible scale dependence, the scalar to tensor-ratio \( r \) and, perhaps most importantly, the non-Gaussian signatures, quantified by \( n \)-point correlation functions or by polynomials of order \( n \) in Fourier-space. They are of particular interest as there is a relation between the statistical properties of the fields and its dynamics. Additionally, the configuration space dependence of the polynomials yields valuable information on the type of inflationary model (Byun & Bean 2013).

The (possibly non-Gaussian) density fluctuations are subsequently imprinted in the cosmic microwave background (CMB) as temperature anisotropies (Fergusson & Shellard 2009; Fergusson & Shellard 2007; Vielva & Sanz 2009; Fergusson et al. 2010; Pettinari et al. 2013), in the matter distribution which can be probed by e.g. gravitational lensing and in the number density of galaxies. Hereby it is advantageous that the observable is linear in the field whose statistical property we investigate. In case of linear dependence the \( n \)-point functions of the observable field can be mapped directly onto the corresponding \( n \)-point function of the primordial density perturbation, which reflects the microphysics of the early Universe.

The first important measurement quantifying non-Gaussianity is the parameter \( f_{NL} \) which describes the skewness of inflationary fluctuations and determines the amplitude of the bispectrum. Not only the bispectrum but also the trispectrum can successfully be constrained by future precisions measurements, where the parameters \( g_{NL} \) and \( \tau_{NL} \) determine the trispectrum amplitude. The complementary analysis of both the bi- and the trispectra in the future experiments will make us able to extract more information about the mechanism of generating the primordial curvature perturbations and constrain the model of the early Universe. Therefore, it is an indispensable task for cosmology to obtain the configuration space dependence for the higher polyspectra and to make clear predictions for the non-Gaussianity parameters. The

non-Gaussianities are commonly expressed as perturbations of modes of the potential \( \propto k^{1/2} \), but can in principle have scale dependences (Chen 2005; Lo Verde et al. 2008; Sefusatti et al. 2009; Riotto & Sloth 2011; Byrnes et al. 2010; Becker et al. 2011; Byrnes et al. 2010).

The first cosmological data release of the Planck satellite has resulted in the highest ever constraints on \( f_{\text{NL}} \) and \( \tau_{\text{NL}} \) (Planck Collaboration et al. 2013a). For the local bispectrum, \( f_{\text{NL}} = 2.7 \pm 5.8 \), with the 1σ confidence level quoted, while the 95% upper bound on the trispectrum parameter is \( \tau_{\text{NL}} \leq 2800 \). The \( f_{\text{NL}} \) is about a factor of 4 improvement over the WMAP bound (Bennett et al. 2012; Giannantonio et al. 2013), while the \( \tau_{\text{NL}} \) bound is improved by about an order of magnitude (Hikage & Matsubara 2012). No Planck bound on \( g_{\text{NL}} \) has yet been made, the tightest bound is currently \( g_{\text{NL}} = (-3.3 \pm 2.2) \times 10^4 \) from WMAP9 data (Sekiguchi & Sugiyama 2013). Previous CMB constraints were made in (Hikage et al. 2008; Smindt et al. 2010; Fergusson et al. 2010). The bound on \( f_{\text{NL}} \) is close to cosmic variance limited for any CMB experiment, for the trispectrum parameters the bounds may still improve by a factor of a few, see e.g. (Smindt et al. 2010; Fergusson et al. 2010; Sekiguchi & Sugiyama 2013).

An alternative way of constraining non-Gaussianities are the number density of clusters as a function of their mass, see Fedeli et al. (2011); Lo Verde & Smith (2011); Enqvist et al. (2011) who show that constraints of order \( 10^2 \) on \( f_{\text{NL}} \) and \( 10^3 \) on \( g_{\text{NL}} \).

In comparison to other probes, weak gravitational lensing provides weaker bounds, but non-Gaussianities have nevertheless important implications for weak lensing. Although the weak lensing bispectrum is by far dominated by structure formation non-Gaussianities (Takada & Jain 2003; Bernardeau et al. 2003; Takada & Jain 2004), whose observational signature has been detected at high significance, (via the quasar magnification bias and the aperture mass skewness, Ménard et al. 2003; Sembolini et al. 2011, respectively), there are a number of studies focusing on primordial non-Gaussianities, for example weak lensing peak counts (Marian et al. 2011), yielding \( \sigma_{\text{NL}} = 10 \) constraints on non-Gaussianities, or topological measures of the weak lensing map, for instance the skeleton (Fedeli et al. 2011) or Minkowski functionals (Munshi et al. 2011). Direct estimation of the inflationary weak lensing bispectra is possible (Pace et al. 2011; Schäfer et al. 2012) but suffers from the Gaussianising effect of the line of sight-integration (Jeong et al. 2011b). Similar to the weak lensing spectrum, bispectra also suffer from contamination by intrinsic alignments (Sembolini et al. 2008) and baryonic physics (Sembolini et al. 2011).

The description of inflationary non-Gaussianities is done in a perturbative way and for the relative magnitude of non-Gaussianities of different order the Suyama-Yamaguchi (SY) relation applies (Suyama & Yamaguchi 2008; Suyama et al. 2010a; Lewis 2011; Smith et al. 2011; Sugiyama 2012; Assassi et al. 2012; Kehagias & Riotto 2012; Beltrán Almeida et al. 2013; Rodriguez et al. 2013; Tasi nato et al. 2013), which in the most basic form relates the amplitudes of the bi- and of the trispectrum. Recently, it has been proposed that testing for a violation of the SY-inequality would make it possible to distinguish between different classes of inflationary models. In this work we focus on the relative between the non-Gaussianity parameters \( f_{\text{NL}} \) and \( \tau_{\text{NL}} \) for a local model, and investigate how well the future EUCLID survey can probe the SY-relation. The question we address is how likely would we believe in the SY-inequality with the inferred \( f_{\text{NL}} \) and \( \tau_{\text{NL}} \)-values. We accomplish this by studying the Bayesian evidence (Trotta 2007, 2008) providing support for the SY-inequality.

Models in which in a single field generates the primordial curvature perturbation predict an equality between one term of the trispectrum and the bispectrum, \( \tau_{\text{NL}} = (\frac{6f_{\text{NL}}}{5})^2 \) (provided that the loop corrections are not anomalously large, if they are then \( g_{\text{NL}} \) should also be observable Tasi nato et al. 2013). Violation of this consistency relation would prove that more than one light field present during inflation had to contribute towards the primordial curvature perturbation. However a verification of the equality would not imply single field inflation, rather that only one of the fields generated perturbations. In fact any detection of non-Gaussianity of the local form will prove that more than one field was present during inflation, because single field inflation predicts negligible levels of local non-Gaussianity. A detection of \( \tau_{\text{NL}} > (\frac{6f_{\text{NL}}}{5})^2 \) would prove that not only that inflation was of the multi-field variety, but also that multiple-fields contributed towards the primordial perturbations, which are the seeds which gave rise to all the structure in the universe today.

A violation of the Suyama-Yamaguchi inequality would come as a big surprise, since the inequality has been proved to hold for all models of inflation. Even more strongly, in the limit of an infinite volume survey it holds true simply by the definitions of \( \tau_{\text{NL}} \) and \( f_{\text{NL}} \), regardless of the theory relating to the primordial perturbations. However since realistic surveys will always have a finite volume, a breaking of the inequality could occur. It remains unclear how one should interpret a breaking of the inequality, and whether any concrete scenarios can be constructed in which this would occur. A violation may be related to a breaking of statistical homogeneity (Smith et al. 2011).

After a brief summary of cosmology and structure formation in Sect. 2 we introduce primordial non-Gaussianities in Sect. 3 along with the SY-inequality relating the relative non-Gaussianity strengths in the polyspectra of different order. The mapping of non-Gaussianities by weak gravitational lensing is summarised in Sect. 4. Then, we investigate the attainable signal to noise-ratios (Sect. 5), address degeneracies in the measurement of \( g_{\text{NL}} \) and \( \tau_{\text{NL}} \) in (Sect. 6), carry out statistical tests of the SY-inequality (Sect. 7) and investigate analytical distributions of ratios of non-Gaussianity parameters (Sect. 8). We summarise our main results in Sect. 9.

The reference cosmological model used is a spatially flat \( \Lambda \)CDM cosmology with adiabatic initial perturbations for the cold dark matter. The specific parameter choices are \( \Omega_m = 0.25, n_s = 1, \sigma_8 = 0.8, \Omega_b = 0.04 \). The Hubble parameter is set to \( h = 0.7 \) and the Hubble-distance is given by \( c/H_0 = 2996.9 \text{ Mpc}/h \). The dark energy equation of state is assumed to be constant with a value of \( w = -0.9 \). We prefer to work with these values that differ slightly from the recent PLANCK results (Planck Collaboration et al. 2013b) because lensing prefers lower \( \Omega_m \)-values and larger \( h \)-values (Heymans et al. 2013). Scale-invariance for \( n_s \) was chosen for simplicity and should not strongly affect the conclusions as the range of angular scales probed is small and close to the normalisation scale.

The fluctuations are taken to be Gaussian perturbed with weak non-Gaussianities of the local type, and for the weak lensing survey we consider the case of EUCLID, with a sky coverage of \( f_{\text{sky}} = 1/2 \), a median redshift of 0.9, a yield of \( h = 40 \) galaxies/arcmin\(^2\) and an ellipticity shape noise of \( \sigma_{\epsilon} = 0.3 \) (Amara & Refregier 2007; Refregier 2009).

\section{Cosmology and Structure Formation}

In spatially flat dark energy cosmologies with the matter density parameter \( \Omega_m \), the Hubble function \( H(a) = \frac{d \ln \Omega}{d \ln a} \) is given by
\[
\frac{H^2(a)}{H_0^2} = \frac{\Omega_m}{a^3} + \frac{1 - \Omega_m}{a^{3(1+w)}},
\]
for a constant dark energy equation of state parameter \(w\). The comoving distance \(\chi\) and scale factor \(a\) are related by
\[
\chi = c \int_a^1 \frac{da}{a^2 H(a)},
\]
given in units of the Hubble distance \(\chi_H = c/H_0\). For the linear matter power spectrum \(P(k)\) which describes the Gaussian fluctuation properties of the linearly evolving density field \(\delta\),
\[
\langle \delta(k)\delta(k') \rangle = (2\pi)^3 \delta_D(k+k') P(k)
\]
the ansatz \(P(k) \sim k^{n_s} T^2(k)\) is chosen with the transfer function \(T(k)\), which is well approximated by the fitting formula
\[
T(q) = \frac{\ln(1 + 2.34q)}{2.34q} \times \left[ 1 + 3.89q + (16.1q)^2 + (5.46q)^3 + (6.71q)^4 \right]^{1/4},
\]
for low-matter density cosmologies (Bardeen et al. 1986). The wave vector \(k = q \Gamma\) enters rescaled by the shape parameter \(\Gamma\) (Sugiyama 1995),
\[
\Gamma = \Omega_m h \exp \left[ -\Omega_b \left( 1 + \frac{\sqrt{27}}{\Omega_m} \right) \right].
\]
The fluctuation amplitude is normalised to the variance \(\sigma^2_k\),
\[
\sigma^2_R = \int k^2 dk \frac{W^2(k)}{2\pi^2} P(k),
\]
with a Fourier-transformed spherical top-hat \(W_\ell(k) = 3 j_\ell(kR)/(kR)\) as the filter function operating at \(R = 8\) Mpc/\(h\). \(j_\ell(x)\) denotes the spherical Bessel function of the first kind of order \(\ell\) (Abramowitz & Stegun 1972). The linear growth of the density field, \(\delta(x,a) = D_s(a)\delta(x,a = 1)\), is described by the growth function \(D_s(a)\), which is the solution to the growth equation (Turner & White 1997; Wang & Steinhardt 1998; Linder & Jenkins 2003),
\[
\frac{d^2}{da^2} D_s(a) + \frac{1}{a} \left( 3 + \frac{d \ln H}{d \ln a} \right) \frac{d}{da} D_s(a) = \frac{3}{2\pi^2} \Omega_m(a) D_s(a).
\]
From the CDM-spectrum of the density perturbation the spectrum of the Newtonian gravitational potential can be obtained
\[
P_\Phi(k) = \left( \frac{3\Omega_m}{2 \chi_H^2} \right)^2 k^{n_s-4} T(k)^2
\]
by application of the Poisson-equation which reads \(\Delta \Phi = 3 \Omega_m/(2 \chi_H^2) \delta\) in comoving coordinates at the current epoch, \(a = 1\).

### 3 NON-GAUSSIANITIES

Inflation has been a very successful paradigm for understanding the origin of the perturbations we observe in different observational channels today. It explains in a very sophisticated way how the universe was smoothed during a quasi-de Sitter expansion while allowing quantum fluctuations to grow and become classical on superhorizon scales. In its simplest implementation, inflation generically predicts almost Gaussian density perturbations close to scale-invariance. In the most basic models of inflation fluctuations originate from a single scalar field in approximate slow roll and deviations from the ideal Gaussian statistics is caused by deviations from the slow-roll conditions. Hence, a detection of non-Gaussianity would be indicative of the shape of the inflaton potential or would imply a more elaborate inflationary model. Although there is consensus that competitive constraints on the non-Gaussianity parameters will emerge from CMB-observations and the next generation of large-scale structure experiments, non-Gaussianities beyond the trispectrum will remain difficult if not impossible to measure. For that reason, we focus on the extraction of bi- and trispectra from lensing data and investigate constraints on their relative magnitude.

Local non-Gaussianities are described as quadratic and cubic perturbations of the Gaussian potential \(\Phi_c(x)\) at a fixed point \(x\), which yields in the single-source case the resulting field \(\Phi(x)\) (LoVerde & Smith 2011),
\[
\Phi_c(x) \rightarrow \Phi(x) = \Phi_c(x) + f_{NL} \left( \Phi_c^2(x) - 2\Phi_c^3(x) \right) + r_{NL} \left( 3\Phi_c^2(x) - 3(\Phi_c^2)^2 \Phi_c(x) \right),
\]
with the parameters \(f_{NL}\), \(r_{NL}\) and \(t_{NL}\). These perturbations generate in Fourier-space a bispectrum \((\Phi(k_1)\Phi(k_2)\Phi(k_3))) = (2\pi)^3 \delta_D(k_1 + k_2 + k_3) B_\Phi(k_1, k_2, k_3)
\[
B_\Phi(k_1, k_2, k_3) = \left( \frac{3\Omega_m}{2 \chi_H^2} \right)^3 2f_{NL} \left( k_1 k_2 k_3 \right)^{n_s+4} + 2 \text{ perm.} \ T(k_1)T(k_2)T(k_3),
\]
and a trispectrum \((\Phi(k_1)\Phi(k_2)\Phi(k_3)\Phi(k_4))) = (2\pi)^3 \delta_D(k_1 + k_2 + k_3 + k_4) T_\Phi(k_1, k_2, k_3, k_4)
\[
T_\Phi(k_1, k_2, k_3, k_4) = \left( \frac{3\Omega_m}{2 \chi_H^2} \right)^4 6g_{NL} \left( k_1 k_2 k_3 k_4 \right)^{n_s+4} + 3 \text{ perm.} + \frac{25}{9} r_{NL} \left( k_1^{-4} k_2^{-4} |k_1 + k_2|^{n_s+4} + 11 \text{ perm.} \right) T(k_1)T(k_2)T(k_3)T(k_4).
\]

4 Weak gravitational lensing

4.1 Weak lensing potential and convergence

Weak gravitational lensing probes the tidal gravitational fields of the cosmic large-scale structure by the distortion of light bundles (for reviews, please refer to Bartelmann & Schneider 2001; Bartelmann 2010). This distortion is measured by the correlated deformation of galaxy ellipticities. The projected lensing potential $\psi$, from which the distortion modes can be obtained by double differentiation,

$$\psi = 2 \int d\chi \ W_0(\chi) \Phi$$

is related to the gravitational potential $\Phi$ by projection with the weighting function $W_0(\chi)$,

$$W_0(\chi) = \frac{D_s(\alpha)}{a} \frac{G(\chi)}{\chi}.$$  

(13)

Born-type corrections are small for both the spectrum (Krause & Hirata 2010) and the bispectrum (Dodelson & Zhang 2005) compared to the lowest-order calculation. The distribution of the lensed galaxies in redshift is incorporated in the function $G(\chi)$,

$$G(\chi) = \int_\chi^{\chi_\alpha} d\chi' \ p(\chi') \frac{dz}{d\chi'} \left(1 - \frac{\chi'}{\chi}\right)$$

with $dz/d\chi' = H(\chi')/c$. It is common in the literature to use the parameterisation

$$p(z)dz = p_0 \left(\frac{z}{z_0}\right)^2 \ exp\left(-\frac{\left(z/z_0\right)^3}{\beta}\right) \ dz \ \text{with} \ \frac{1}{p_0} = \frac{z_0}{\beta} \Gamma\left(\frac{3}{\beta}\right).$$

(15)

Because of the linearity of the observables following from eqn. (12) moments of the gravitational potential are mapped onto the same moments of the observable with no mixing taking place. At this point we would like to emphasis that the non-Gaussianity in the weak lensing signal is diluted by the line of sight integration, which, according to the central limit theorem, adds up a large number of non-Gaussian values for the gravitational potential with the consequence that the integrated lensing potential contains weaker non-Gaussianities (Jeong et al. 2011b).

4.2 Convergence polyspectra

Application of the Limber-equation and repeated substitution of $\kappa = \ell^2 \psi/2$ allows the derivation of the convergence spectrum $C_\kappa(\ell)$ from the spectrum $P_\kappa(k)$ of the gravitational potential,

$$C_\kappa(\ell) = \ell^4 \int_0^{\chi_\alpha} \frac{dz}{\chi} \ W_0^2(\chi) P_\kappa(k),$$

(16)

of the the convergence bispectrum $B_\kappa(\ell_1, \ell_2, \ell_3)$,

$$B_\kappa(\ell_1, \ell_2, \ell_3) = (\ell_1 \ell_2 \ell_3)^2 \int_0^{\chi_\alpha} \frac{dz}{\chi} \ W_0^3(\chi) B_\kappa(k_1, k_2, k_3),$$

(17)

and of the convergence trispectrum $T_\kappa(\ell_1, \ell_2, \ell_3, \ell_4)$,

$$T_\kappa(\ell_1, \ell_2, \ell_3, \ell_4) = (\ell_1 \ell_2 \ell_3 \ell_4)^2 \int_0^{\chi_\alpha} \frac{dz}{\chi} \ W_0^4(\chi) T_\kappa(k_1, k_2, k_3, k_4).$$

(18)

This relation follows from the expansion of the tensor $\psi = \nabla^2 \phi / \nabla \theta_0 \partial \theta_0$ into the basis of all symmetric $2 \times 2$-matrices provided by the Pauli matrices $\sigma_i$ (A Abramowitz & Stegun 1972). In particular, the lensing convergence is given by $\kappa = \text{tr}(\psi \sigma_0)/2 = \Delta \psi/2$ with the unit matrix $\sigma_0$. Although the actual observable in lensing are the weak shear components $\gamma_+ = \text{tr}(\psi \sigma_1)/2$ and $\gamma_- = \text{tr}(\psi \sigma_3)/2$, we present all calculations in terms of the convergence, which has identical statistical properties and being scalar, is easier to work with.

Fig. 1 shows the weak lensing spectrum and the non-Gaussian bi- and trispectra as a function of multipole order $\ell$. For the bispectrum we choose an equatorial configuration and for the trispectrum a square one, which are in fact lower bounds on the bi- and trispectrum amplitudes for local non-Gaussianities. The polyspectra are multiplied with factors of $(\ell)^{2n}$ for making them dimensionless and in that way we were able to show all spectra in a single plot, providing a better physical interpretation of variance, skewness and kurtosis per logarithmic $\ell$-interval. In our derivation we derive the lensing potential directly from the gravitational potential, in which the polyspectra are expressed and subsequently apply $\ell^2$-prefactors to obtain the polyspectra in terms of the weak lensing convergence, for which the covariance and the noise of the measurement is most conveniently expressed. The disadvantage of this method is that the $\tau_{NL}$-part of the trispectrum $T_\kappa$ diverges

SY-inequality and weak lensing

Figure 1. The weak convergence spectrum $C_\ell(\ell)$ (red solid line), the weak convergence bispectrum for the equilateral configuration $B_\ell(\ell)$ for an equilateral configuration (green solid line) with $f_{\text{NL}} = 1$, and the convergence trispectrum $T_\ell(\ell)$ for a square configuration as a function of multipole order $\ell$, for $g_{\text{NL}} = 1$ (blue dashed line).

Figure 2. Contributions $dC_\ell(\ell)/d\chi$ (red lines), $dB_\ell(\ell)/d\chi$ (green lines) for the equilateral configuration and $dT_\ell(\ell)/d\chi$ (blue lines) for the square configuration, as a function of comoving distance $\chi$. The non-Gaussianity parameters are chosen to be $f_{\text{NL}} = 1$ and $g_{\text{NL}} = 1$. We compare the contributions at $\ell = 10$ (solid line) with $\ell = 100$ (dashed line) and $\ell = 1000$ (dash-dotted line).

for the square configuration, because opposite sides of the square cancel in the $|k_i - k_{i+2}|$-terms which can not be exponentsiated with a negative number $n_s - 4$. We control this by never letting the cosine of the angle between $k_i$ and $k_{i+2}$ drop below $-0.95$. We verified that this exclusion cone of size $\approx 20^\circ$ has a minor influence on the computation of signal to noise-ratios.

The contributions to the weak lensing polyspectra as a function of comoving distance $\chi$ are shown in Fig. 2, which is the derivative of Fig. 1 at fixed $\ell$. At the same time, the plot presents the integrand of the Limber equation and it demonstrates nicely that the largest contribution to the weak lensing polyspectra comes from the peak of the galaxy distribution, with small variations with multipole order as higher multipoles acquire contributions from slightly lower distances.

### 4.3 Relative magnitudes of weak lensing polyspectra

The strength of the non-Gaussianity introduced by nonzero values of $g_{\text{NL}}$ and $\tau_{\text{NL}}$ can be quantified by taking ratios of the three polyspectra. We define the skewness parameter $S(\ell)$ as the ratio

$$S(\ell) = \frac{B_\ell(\ell)}{C_\ell(\ell)^{3/2}}$$

(19)
between the convergence bispectra for the equilateral configuration and the convergence spectrum. In analogy, we define the kurtosis parameter \( K(\ell) \),

\[
K(\ell) = \frac{T(\ell)}{C(\ell)^2},
\]

as the ratio between the convergence trispectrum for the square configuration and the spectrum as a way of quantifying the size of the non-Gaussianity. The relative magnitude of the bi- and trispectrum is given by the function \( Q(\ell) \),

\[
Q(\ell) = \frac{T(\ell)}{B(\ell)^{1/3}}.
\]

For computing the three parameters we set the non-Gaussianity parameters to \( f_{\text{NL}} = g_{\text{NL}} = 1 \).

The parameters are shown in Fig. 3 as a function of multipole order \( \ell \). They have been constructed such that the transfer function \( T(k) \) in each of the polyspectra is cancelled. The parameters are power-laws because the inflationary part of the spectrum \( k^{-4} \) is scale-free and the Wick theorem reduces the polyspectra to products of that inflationary spectrum. The amplitude of the parameters reflects the proportionality of the polyspectra to \( 3\Omega_m/(2\pi^2) \) and the normalisation of each mode proportional to \( \sigma_s \). A noticeable outcome in the plot is the fact that the ratio is largest on large scales as anticipated, because the fluctuations in the inflationary fields give rise to fluctuations in the gravitational potential on which the perturbation theory is built. Since the effect of the potential is on large scale and the trispectrum is proportional to the spectrum taken to the third power, the ratio \( K(\ell) \) should be the largest on large scales. Therefore as one can see in the Fig. 3 the ratio drops to very small numbers on small scales. Similar arguments apply to \( Q(\ell) \) and \( S(\ell) \), although the dependences are weaker.

## 5 SIGNAL TO NOISE-RATIOS

The signal strength at which a given polyspectrum can be measured is computed as the ratio between that particular polyspectrum and the variance of its estimator averaged over a Gaussian ensemble (which, in the case of structure formation non-Gaussianities, has been shown to be a serious limitation Takada & Jain 2009; Sato & Nishimichi 2013; Kayo et al. 2013). We work in the flat-sky approximation because the treatment of the bi- and trispectra involves a configuration-space average, which requires the evaluation of Wigner-symbols in multipole space.

In the flat-sky approximation the signal to noise ratio \( \Sigma_c \) of the weak convergence spectrum \( C_c(\ell) \) reads (Tegmark et al. 1997; Cooray & Hu 2001)

\[
\Sigma_c^2 = \int \frac{d^3\ell}{(2\pi)^3} \frac{C_c(\ell)^2}{\text{cov}_c(\ell)}
\]

with the Gaussian expression for the covariance \( \text{cov}_c(\ell) \) (Hu & White 2001; Takada & Hu 2013),

\[
\text{cov}_c(\ell) = \frac{1}{f_{\text{sky}}} \frac{2}{2\pi} C_c(\ell)^2.
\]

Likewise, the signal to noise ratio \( \Sigma_b \) of the bispectrum \( B_b(\ell) \) is given by (Hu 2000; Takada & Jain 2004; Babich 2005; Joachimi et al. 2009)

\[
\Sigma_b^2 = \int \frac{d^3\ell_1}{(2\pi)^3} \int \frac{d^3\ell_2}{(2\pi)^3} \int \frac{d^3\ell_3}{(2\pi)^3} \frac{B_b(\ell_1, \ell_2, \ell_3)}{\text{cov}_b(\ell_1, \ell_2, \ell_3)}
\]
provides a plot of the polyspectra in units of the noise of their respective estimators. Clearly, the measurements are dominated by

where we plot the likelihood contours Gaussian and are therefore described by the noisy convergence spectrum $\tilde{\kappa}_\ell$ in principle be compensated by resorting to tomographic weak lensing (see Sect. 6).

Finally, the signal to noise ratio $\Sigma_\ell$ of the convergence trispectrum $T_\ell$ results from (Zaldarriaga 2000; Hu 2001; Kamionkowski et al. 2011)

with the expression

for the trispectrum covariance $\text{cov}_\ell$. In all covariances, the fluctuations of the weak lensing signal and the noise are taken to be Gaussian and are therefore described by the noisy convergence spectrum $\tilde{C}_\ell$,

with the number of galaxies per steradian $n$ and the ellipticity noise $\sigma_\epsilon$.

The configuration space integrations for estimating the signal to noise ratios as well as for computing Fisher-matrices are carried out in polar coordinates with a Monte-Carlo integration scheme (specifically, with the CUBA-library by Hahn 2005, who provides a range of adaptive Monte-Carlo integration algorithms). We obtained the best results with the SUAVE-algorithm that uses importance sampling for estimating the values of the integrals.

Fig. 4 provides a plot of the polyspectra in units of the noise of their respective estimators. Clearly, the measurements are dominated by cosmic variance and show the according Poissonian dependence with multipole $\ell$, before the galaxy shape noise limits the measurement on small scales and the curves level off or, in the case of the higher polyspectra, begin to drop on multipoles $\ell \gtrsim 300$.

An observation of the polyspectra $C_\ell$, $B_\ell$ and $T_\ell$ with EUCLID would yield signal to noise ratios as depicted in Fig. 5. Whereas the convergence spectrum $C_\ell$ can be detected with high significance in integrating over the multipole range up to $\ell = 10^3$, the bispectrum would require $f_{\text{NL}}$ to be of the order $10^2$ and the two trispectrum non-Gaussianities $g_{\text{NL}}$ and $\tau_{\text{NL}}$-values of the order $10^6$ for yielding a detection, which of course is weaker compared to CMB bounds or bounds on the parameters from large-scale structure observation. The reason lies in the non-Gaussianity suppression due to the central-limit theorem in the line of sight-integration (Jeong et al. 2011b). This could in principle be compensated by resorting to tomographic weak lensing (see Sect. 9).

6 DEGENERACIES IN THE TRISPECRTUM

The independency of estimates of $g_{\text{NL}}$ and $\tau_{\text{NL}}$ from the weak lensing trispectrum are depicted in Fig. 6 where we plot the likelihood contours in the $g_{\text{NL}}$-$\tau_{\text{NL}}$-plane. The likelihood $L(f_{\text{NL}}, g_{\text{NL}}, \tau_{\text{NL}})$ is taken to be Gaussian,

$$L(f_{\text{NL}}, g_{\text{NL}}, \tau_{\text{NL}}) = \frac{\text{det}(F)}{(2\pi)^{3/2}} \exp \left[ -\frac{1}{2} \begin{pmatrix} f_{\text{NL}} & g_{\text{NL}} & \tau_{\text{NL}} \end{pmatrix}^T F \begin{pmatrix} f_{\text{NL}} & g_{\text{NL}} & \tau_{\text{NL}} \end{pmatrix} \right]$$

Figure 5. Cumulative signal to noise-ratios $\Sigma_C$ for the weak lensing spectrum (red solid line), $\Sigma_B$ for the weak lensing bispectrum (green solid line) and $\Sigma_T$ for the weak lensing trispectrum, for $(\tau_{NL}, g_{NL}) = (1, 1)$ (blue solid line), $(\tau_{NL}, g_{NL}) = (1, 0)$ (blue dashed line) and $(\tau_{NL}, g_{NL}) = (0, 1)$ (blue dash-dotted line).

Figure 6. Degeneracies in the $g_{NL}$-$\tau_{NL}$-plane for a measurement with EUCLID: The 1σ . . . 4σ-contours of the joint likelihood are drawn, while all cosmological parameters are assumed to be known exactly.

which can be expected due to the linearity of the polyspectra with the non-Gaussianity parameters. The Fisher-matrix $F$ has been estimated for a purely Gaussian reference model and with a Gaussian covariance, and its entries can be computed in analogy to the signal to noise ratios. The diagonal of the Fisher matrix is composed from the values $\Sigma_B$ and $\Sigma_T$ with the non-Gaussianity parameters set to unity, and the only off-diagonal elements are the two entries $F_{g_{NL}\tau_{NL}}$.

$$F_{g_{NL}\tau_{NL}} = \int \frac{d^2 \ell_1}{(2\pi)^2} \int \frac{d^2 \ell_2}{(2\pi)^2} \int \frac{d^2 \ell_3}{(2\pi)^2} \int \frac{d^2 \ell_4}{(2\pi)^2} \frac{1}{\text{cov}_T(\ell_1, \ell_2, \ell_3, \ell_4)} T_s(\ell_1, \ell_2, \ell_3, \ell_4),$$

which again is solved by Monte-Carlo integration in polar coordinates. Essentially, the diagonal elements of the Fisher matrix are given by the inverse squared signal to noise ratios since $B_\kappa \propto f_{NL}$ and $T_\kappa \propto \tau_{NL}$. For Gaussian covariances, the statistical errors on $f_{NL}$ on one side and $g_{NL}$ and $\tau_{NL}$ on the other are independent, since $F_{f_{NL}\tau_{NL}} = 0 = F_{f_{NL}g_{NL}}$. Clearly, there is a degeneracy that $g_{NL}$ can be increased at the expense of $\tau_{NL}$ and vice versa. In the remainder of the paper, we carry out a marginalisation of the Fisher-matrix such that the uncertainty in $g_{NL}$ is contained in $\tau_{NL}$. The overall precision that can be reached with lensing is about an order of magnitude worse compared to the CMB (Smidt et al. 2010), with a very similar orientation of the degeneracy.

7 TESTING THE SUYAMA-YAMAGUCHI-INEQUALITY

Given the fact that there are a vast array of different inflationary models generating local-type non-Gaussianity, it is indispensable to have a classification of these different models into some categories. This can be for instance achieved by using consistency relations among the non-Gaussianity parameters as the SY-relation. In the literature one distinguishes between three main categories of models, the single-source model, the multi-source model and constrained multi-source model. As the name already reveals the single-source model is a model of one field causing the non-linearities. The important representatives of this category include the pure curvaton and the pure modulated reheating scenarios. It is also possible that multiple sources are simultaneously responsible for the origin of density fluctuations. It could be for instance that both the inflaton and the curvaton fields are generating the non-linearities we observe today. In the case of multi-source models the relations between the non-linearity parameters are different from those for the single-source models. Finally, the constrained multi-source models are models in which the loop contributions in the expressions for the power spectrum and non-linearity parameters are not neglected. The classification into these three categories was based on the relation between $f_{\text{NL}}$ and $\tau_{\text{NL}}$ (Suyama et al. 2010b). Nevertheless, this will not be enough to discriminate between the models of each category. For this purpose, we will need further relations between $f_{\text{NL}}$ and $g_{\text{NL}}$. Hereby, the models are distinguished by rather if $g_{\text{NL}}$ is proportional to $f_{\text{NL}}$ ($f_{\text{NL}} \sim g_{\text{NL}}$) or enhanced or suppressed compared to $f_{\text{NL}}$. Summarizing, the $f_{\text{NL}}-\tau_{\text{NL}}$ and $f_{\text{NL}}-g_{\text{NL}}$ relations will be powerful tools to discriminate models well. In this work we are focusing on the SY-relation between $f_{\text{NL}}$ and $\tau_{\text{NL}}$. The Bayesian evidence (for reviews, see Trotta 2007, 2008) for the SY-relation $\tau_{\text{NL}} \geq (6f_{\text{NL}}/5)^2$ can be expressed as the fraction $\alpha$ of the likelihood $L$ that provides support:

$$\alpha = \int_{\tau_{\text{NL}} \geq (6f_{\text{NL}}/5)^2} d\tau_{\text{NL}} \int d^2f_{\text{NL}} L(f_{\text{NL}} - f_{\text{NL}}, \tau_{\text{NL}} - \tau_{\text{NL}}).$$

(Hence $\alpha$ answers the question as to how likely one would believe in the SY-inequality with inferred $f_{\text{NL}}$ and $\tau_{\text{NL}}$-values if the true values are given by $f_{\text{NL}}$ and $\tau_{\text{NL}}$. Technically, $\alpha$ corresponds to the integral over the likelihood in the $f_{\text{NL}}$-$\tau_{\text{NL}}$-plane over the allowed region. If $\alpha = 1$, we would fully believe in the SY-inequality, if $\alpha = 0$ we would think that the SY-relation is violated. Correspondingly, $1 - \alpha$ would provide a quantification of the violation of the SY-relation,

$$1 - \alpha = \int_{\tau_{\text{NL}} \leq (6f_{\text{NL}}/5)^2} d\tau_{\text{NL}} \int d^2f_{\text{NL}} L(f_{\text{NL}} - f_{\text{NL}}, \tau_{\text{NL}} - \tau_{\text{NL}}).$$

We can formulate the integration over the allowed region as well as an integration over the full $f_{\text{NL}}$-$\tau_{\text{NL}}$-range of the likelihood multiplied with a suitable function $\Pi$,

$$\alpha = \int d\tau_{\text{NL}} \int d^2f_{\text{NL}} L(f_{\text{NL}} - f_{\text{NL}}, \tau_{\text{NL}} - \tau_{\text{NL}}) \times \Pi(f_{\text{NL}}, \tau_{\text{NL}})$$

with $\Pi = \theta(\tau_{\text{NL}} - (6f_{\text{NL}}/5)^2)$. This function would play the role of a theoretical prior in the $f_{\text{NL}}$-$\tau_{\text{NL}}$-plane. In this interpretation, $\alpha$ corresponds to the Bayesian evidence, that means the degree of belief that the SY-inequality is correct.

We can test the SY-inequality $\tau_{\text{NL}} \geq (6f_{\text{NL}}/5)^2$ up to the errors on $f_{\text{NL}}$ and $\tau_{\text{NL}}$ provided by the lensing measurement: Fig. 7 shows the test statistic $\alpha(f_{\text{NL}}, g_{\text{NL}}, \tau_{\text{NL}})$ in the $f_{\text{NL}}$-$\tau_{\text{NL}}$-plane, where the likelihood has been marginalised over the parameter $g_{\text{NL}}$. The blue regime $f_{\text{NL}} \sim 10^2$ is the parameter space which would not fulfill the SY-inequality, whereas the green area $\tau_{\text{NL}} \sim 10^3$ is the parameter space where the SY-relation would be fulfilled. Values of $f_{\text{NL}} \sim 10^2$ and $\tau_{\text{NL}} \sim 10^3$ are inconclusive and even though non-Gaussianity parameters may be inferred that would be in violation of the SY-relation, the wide likelihood would not allow to derive a statement. Another nice feature is the fact that for large $f_{\text{NL}}$ and $\tau_{\text{NL}}$ the relation can be probed to larger precision and the contours are more closely spaced.

In models where the field which generates non-Gaussianity has a quadratic potential, the non-Gaussianity is mainly captured by the relation $\tau_{\text{NL}} \sim (6f_{\text{NL}}/5)^2$. Thus we can write the above equality as

$$\tau_{\text{NL}} \sim \frac{6f_{\text{NL}}}{5} \sqrt{\tau_{\text{NL}}}$$

where the probability distribution $p_{\text{NL}}(x)$ is given by

$$p_{\text{NL}}(y) = \frac{p_{\text{NL}}(\sqrt{y})}{2\sqrt{y}}$$

8 ANALYTICAL DISTRIBUTIONS

In this section we derive the analytical expression for the probability density that the SY-relation is exactly fulfilled, $\tau_{\text{NL}} = (6f_{\text{NL}}/5)^2$, i.e. for the case $(6f_{\text{NL}}/5)^2/\tau_{\text{NL}} = 1$. For this purpose we explore the properties of the distribution

$$p(Q) dQ \quad \text{with} \quad Q = \frac{(6f_{\text{NL}}/5)^2}{\tau_{\text{NL}}}$$

where the parameters $f_{\text{NL}}$ and $\tau_{\text{NL}}$ are both Gaussian distributed with means $f_{\text{NL}}$, $\tau_{\text{NL}}$ and widths $\sigma_{\text{f_{NL}}}$ and $\sigma_{\text{tau_{NL}}}$.

We will split the derivation into two parts. First of all we will derive the distribution for the product $f_{\text{NL}}^2$. For this purpose we use the transformation of the probability density:

$$p_f(y)dy = p_f(x)dx$$

with the Jacobian $dx/dy = 1/(2\sqrt{y})$ and where $x = f_{\text{NL}}$ and $y = x^2$. Thus we can write the above equality as

$$p_f(y) = \frac{p_f(\sqrt{y})}{2\sqrt{y}}$$

© 2013 RAS, MNRAS 000, 1–14
we are illustrating the ratio distribution as a function of shows a number of example distributions Fisher matrix and correspond to an equality. The values for a clearly visible bumped line along the SY-equality. Similarly, Fig. WMAP7 by non-Gaussianity parameters $K$.

Figure 7. Bayesian evidence of $(f_{NL}, \tau_{NL})$ in the $f_{NL}-\tau_{NL}$-plane. Blue regions correspond to low, green regions to high degrees of belief. The SY-relation $\tau_{NL} = (6 f_{NL} / 5)^2$ is indicated by the red dashed line.

$$p_1(y) = \frac{1}{\sqrt{2\pi f_{NL}}} \exp \left( -\frac{(\sqrt{y} - f_{NL})^2}{2 f_{NL}^2} \right).$$ \hfill (37)

Naively written in this way, we would lose half of the distribution and do not obtain the right normalization. Therefore we have to distinguish between the different signs of $y$. The distribution of a square of a Gaussian distributed variate $f_{NL}$ with mean $f_{NL}$ and variance $\sigma_{f_{NL}}$ is given by

$$p_1(y) = \frac{1}{\sqrt{2\pi \sigma_{f_{NL}}^2}} \frac{1}{2 \sqrt{y}} \left\{ \begin{array}{ll}
\exp \left( -\frac{(\sqrt{y} - f_{NL})^2}{2 \sigma_{f_{NL}}^2} \right), & \text{positive branch of } \sqrt{y} \\
\exp \left( -\frac{(\sqrt{y} + f_{NL})^2}{2 \sigma_{f_{NL}}^2} \right), & \text{negative branch of } \sqrt{y}
\end{array} \right. \hfill (38)$$

with $y = f_{NL}^2$. In the special case of normally distributed variates, the above expression would reduce to

$$p_1(y) = \frac{K_0(\sigma_{f_{NL}} \sigma_{\tau_{NL}})}{\pi \sigma_{f_{NL}} \sigma_{\tau_{NL}}}. \hfill (39)$$

where $K_0(y)$ is a modified Bessel function of the second kind (Abramowitz & Stegun 1972).

The next step is now to implement the distribution eqn. (38) into a ratio distribution since we are interested in the distribution of $(6 f_{NL}/5)^2/\tau_{NL}$ incorporating the additional factor. The ratio distribution can be written down using the Mellin transformation (Arfken & Weber 2005):

$$p(Q) = \int |L| d\alpha \ p_1(\alpha Q, f_{NL}) p_1(\alpha, \tau_{NL}).$$ \hfill (40)

with a Gaussian distribution for $z = \tau_{NL}$.

$$p_1(z) = \frac{1}{\sqrt{2\pi \sigma^2}} \exp \left( -\frac{(z - \bar{z})^2}{2 \sigma^2} \right).$$ \hfill (41)

In the special case of Gaussian distributed variates with zero mean the distribution would be simply given by the Cauchy distribution (Marsaglia 1965, 2006), but in the general case eqn. (38) needs to be evaluated analytically.

In Fig. 8 we are illustrating the ratio distribution as a function of $f_{NL}$ and $\tau_{NL}$ for $Q = 1$, i.e. for the case where the SY-relations becomes an equality. The values for $f_{NL}$ run from 1 to $10^3$ and $\tau_{NL}$ runs from 1 to $10^5$. The variances $\sigma_{f_{NL}}$ and $\sigma_{\tau_{NL}}$ are taken from the output of the Fisher matrix and correspond to $\sigma_{f_{NL}} = 93$ and $\sigma_{\tau_{NL}} = 7.5 \times 10^5$. We would like to point out the nice outcome, that the distribution has a clearly visible bumped line along the the SY-equality. Similarly, Fig. 9 shows a number of example distributions $p(Q)dQ$ for a choice of non-Gaussianity parameters $f_{NL}$ and $\tau_{NL}$. We let $Q$ run from 1 to 5 and fix the values $f_{NL} = 10^2$, $10^3$ and $\tau_{NL} = 10^4, 10^5, 10^6$.

Smidt et al. (2010) study possible bounds on $A_{NL} = 1/Q$ based on a combination of CMB probes. The value of $f_{NL} = 32$ suggested by WMAP7Komatsu et al. (2011) would imply that a detection of $\tau_{NL}$ with Planck is possible if $Q < 1/2$, and future experiments such as CorE (The CorE Collaboration et al. 2011) or EPIC (Bock et al. 2008) can probe regions of smaller trispectra, which might be relevant as a number of models predict small bi- and large trispectra, and could be a favourable for detecting non-Gaussianities. In our work we prefer to work with the probability distribution of $Q$ because for small values of $f_{NL}$ as suggested by Planck (Planck Collaboration et al. 2013a) one naturally obtains large values for $\Lambda = 1/Q$.

Figure 9. The probability distribution $p(Q)$ as a function of $Q$ for fixed non-Gaussianity parameter $f_{NL} = 10^2$, $10^3$ (red and blue, respectively) and $\tau_{NL} = 10^4$, $10^5$, $10^6$ (solid, dashed and dash-dotted).

9 SUMMARY

The topic of this paper is an investigation of inflationary bi- and trispectra by weak lensing, and testing of the SY-inequality relating the relative strengths of the inflationary bi- and trispectrum amplitudes using weak lensing as a mapping of the large-scale structure. Specifically, we consider the case of the projected EUCLID weak lensing survey and choose a basic wCDM-cosmology as the background model.

(i) We compute weak lensing potential and weak lensing convergence spectra $C_\kappa$, bispectra $B_\kappa$ and trispectra $T_\kappa$ by Limber-projection from the CDM-polyspectra $P_\Phi$, $B_\Phi$ and $T_\Phi$ of the Newtonian gravitational potential $\Phi$. The non-Gaussianity model for the higher-order spectra are local non-Gaussianities parametrised with $f_{NL}$, $g_{NL}$ and $\tau_{NL}$. The weak lensing polyspectra reflect in their magnitude the perturbative ansatz by which they are generated and collect most of their amplitude at distances of $\sim 1$ Gpc/$h$, where the higher order polyspectra show a tendency to be generated at slightly smaller distances. Ratios of polyspectra where the transfer function has been divided out, nicely illustrate the reduction to products of spectra by application of the Wick theorem, as a pure power-law behaviour is recovered by this construction.
Figure 10. Cumulative signal to noise ratios $\Sigma_s$ (green lines) and $\Sigma_T$ (blue lines) for measuring the convergence bi- and trispectrum in a tomographic weak lensing survey, with $N = 1, 2, 3, 4$ (bottom to top) redshift bins.

(ii) The signal to noise ratios $\Sigma_c$, $\Sigma_B$ and $\Sigma_T$ at which the polyspectra can be estimated with EUCLID’s weak lensing data are forecasted using a very efficient Monte-Carlo integration scheme for carrying out the configuration space summation. These integrations are carried out in flat polar coordinates with a Gaussian expression for the signal covariance. Whereas the first simplification should influence the result only weakly as most of the signal originates from sufficiently large multipoles, the second simplification has been shown to be violated in the investigation of dominating structure formation non-Gaussianities, but might be applicable in the case of weak inflationary non-Gaussianities and on low multipoles.

(iii) With a very similar integration scheme we compute a Fisher-matrix for the set of non-Gaussianity parameters $f_{NL}$, $g_{NL}$ and $\tau_{NL}$ such that a Gaussian likelihood $L$ can be written down. Marginalisation over $g_{NL}$ yields the final likelihood $L(f_{NL}, \tau_{NL})$ which is the basis of the statistical investigations concerning the SY-inequality. The diagonal elements of the Fisher matrix are simply inverse squared signal to noise ratios due to the proportionality $B_s \propto f_{NL}$ and $T_s \propto \tau_{NL}$. For Gaussian covariances, the parameters $f_{NL}$ and $\tau_{NL}$ are statistically independent.

(iv) We quantify the degree of belief in the SY-relation with a set of inferred values for $f_{NL}$ and $\tau_{NL}$ and with statistical errors $\sigma_{f_{NL}}$ and $\sigma_{\tau_{NL}}$ by computing the Bayesian evidence that the SY-relation $\tau_{NL} \geq (6 f_{NL}/5)^2$ is fulfilled. EUCLID data would provide evidence in favour of the relation for $\tau_{NL} \gtrsim 10^2$ and against the relation if $f_{NL} \lesssim 10^2$. For $f_{NL} < 10^2$ and $\tau_{NL} \lesssim 10^5$ the Bayesian evidence is inconclusive and quite generally, large non-Gaussianities allow for a better probing of the relation.

(v) We provide a computation of the probability that the quantity $Q \equiv (6 f_{NL}/5)^2/\tau_{NL}$ is one, i.e. for an exact SY-relation. The distribution can be derived by generating a $\chi^2$-distribution for $f_{NL}^2$ and then by Mellin-transform for the ratio $f_{NL}^2/\tau_{NL}$. We observe, that the analytical probability distribution has a clearly visible bumped line along the SY-equality.

In summary, we would like to point out that constraining non-Gaussianities in weak lensing data is possible but the sensitivity is weaker compared to other probes. Nevertheless, for the small bispectrum parameter confirmed by PLANCK, $\tau_{NL}$ values of the order of $10^5$ would be needed to claim a satisfied SY-relation, and values smaller than that would not imply a violation, given the large experimental uncertainties.

Despite the fact that we will not be able to see a violation of the inequality, if $\tau_{NL}$ is large enough to be observed, then this together with the tight observational constraints on $f_{NL}$ will imply that the single-source relation is broken and instead $\tau_{NL} \gg f_{NL}^2$. Even though this is allowed by inflation, such a result would come as a surprise and be of great interest, since typically even multi-source scenarios predict a result which is close to the single-source equality, and a strong breaking is hard to realise for known models, e.g. Peterson & Tegmark (2011); Elliston et al. (2012); Leung et al. (2013), although examples can be constructed at the expense of fine tuning (Ichikawa et al. 2008; Byrnes et al. 2009).

As an outlook we provide a very coarse projection what levels of $f_{NL}$ and $\tau_{NL}$ can be probed by tomographic surveys (Hu 1999; Takada & Jain 2004) with $N = 2, 3, 4$ redshift bins which are chosen to contain equal fractions of the galaxy distribution, as a way of boosting the sensitivity, to decrease statistical errors and break degeneracies (Kitching et al. 2008; Schäfer & Heisenberg 2012), in our case on the non-Gaussianity parameters. Fig. 10 shows the signal to noise ratio $\Sigma_B$ and $\Sigma_T$ for measuring local weak lensing bi- and trispectra, respectively, and at the same time those numbers correspond to the inverse statistical errors $\sigma_{f_{NL}}$ and $\sigma_{\tau_{NL}}$ because of the proportionality $B_s \propto f_{NL}$ and $T_s \propto \tau_{NL}$. If the measurement is limited by statistics the constraints on the non-Gaussianity parameters could be improved substantially, up to an statistical uncertainty of $\sigma_{f_{NL}}$ of the order 10 and $\sigma_{\tau_{NL}}$ of the order $10^4$ with a correspondingly tighter probing of the SY-relation, but of course many systematical effects become important, related to the measurement itself (Semboloni et al. 2011; Heymans et al. 2013), to structure formation non-Gaussianities at low redshifts (which can in principle be controlled with good priors on cosmological parameters, Schäfer et al. 2012), or to the numerics of the polyspectrum estimation (Smith et al. 2011).
ACKNOWLEDGEMENTS

AG’s and BMS’s work was supported by the German Research Foundation (DFG) within the framework of the excellence initiative through GSFP at Heidelberg and the International Max Planck Research School for astronomy and cosmic physics. LH was supported by the Swiss Science Foundation and CTB acknowledges support from the Royal Society. We would like to thank Gero Jürgens for his support concerning the expressions for the covariance of bi- and trispectra. LH would like to thank to Claudia de Rham and Raquel Ribeiro for very useful discussions.
