For a variety of on-going and planned gravitational-wave (GW) experiments, we study expected constraints on the fraction \( f_{\text{PBH}} \) of primordial black holes (PBHs) in dark matter by evaluating the energy-density spectra of two kinds of stochastic GW backgrounds. The first one is produced from an incoherent superposition of GWs emitted from coalescences of all the binary PBHs. The second one is induced through non-linear mode couplings of large primordial curvature perturbations inevitably associated with the generation of PBHs in the early Universe. In this paper, we focus on the PBHs with their masses of \( 10^{-8} M_\odot \leq M_{\text{PBH}} < 1 M_\odot \), since they are not expected to be of a stellar origin. In almost all ranges of the masses, we show that the experiments are sensitive to constrain the fraction for \( 10^{-3} \leq f_{\text{PBH}} \leq 1 \) by considering the GWs from coalescing events and \( 10^{-10} \lesssim f_{\text{PBH}} \lesssim 1 \) by considering the GWs from curvature perturbations. Exceptionally, only in a narrow range of masses for \( 2 \times 10^{-5} M_\odot \lesssim M_{\text{PBH}} \lesssim 4 \times 10^{-5} M_\odot \), the fraction cannot be constrained for \( f_{\text{PBH}} \lesssim 3 \times 10^{-3} \) by those two GW backgrounds.

I. INTRODUCTION

The first detection of gravitational waves (GWs) from a binary black hole (BBH) merger by the first Advanced LIGO (aLIGO) observing run [1] has revived extensive interests in primordial black holes (PBHs) [2, 3], which are produced directly from the gravitational collapses of the enhanced inhomogeneities in the primordial Universe. Until now, the origin of these black holes (BHs) and the formation mechanism of BBHs are still under debate. Besides an astrophysical origin [4–6], the possibility that these BHs are of a primordial origin is also considered [7–20]. Recently, it has been proposed that the PBHs are capable of accounting for the event rate of BBH mergers observed by aLIGO [7, 8], although the formation mechanisms of PBH binaries bring about uncertainties of a couple of orders of magnitude (see e.g. Ref. [20] and references therein). The PBHs can be one of the most promising candidates for the cold dark matter (CDM) [11]. Currently, the nature of CDM is still uncertain [21]. There is not definitive evidence for the weakly interacting massive particles (WIMPs) which is a prime candidate for CDM [22–26]. Conventionally, one defines the abundance of PBHs in CDM as a dimensionless fraction of the form \( f_{\text{PBH}} = \Omega_{\text{PBH}}/\Omega_{\text{CDM}} \), where \( \Omega_{\text{PBH}} \) and \( \Omega_{\text{CDM}} \) denote the present energy-density fractions of PBHs and CDM, respectively. This quantity has been constrained in a variety of mass ranges by a variety of observations (see e.g. Refs. [20, 27] and references therein), for example, the microlensing events caused by massive astrophysical compact halo objects [28–31], the gas accretion effect of PBHs on the cosmic microwave background (CMB) [32–34], the null detection of a third-order Shapiro time delay using a pulsar timing array [35], and the claimed event rate of BBH mergers from aLIGO [7, 8, 36], etc.

The PBHs can be also a useful probe to the primordial curvature perturbations [37], since the former are formed via directly gravitational collapses of the latter [2, 3]. Contrary to the astrophysical processes for which only BHs heavier than \( O(1) \) solar mass can be produced [38], the small-mass BHs could be also produced by the strong gravity inside the highly compressed overdensities in the early Universe [39]. The PBH mass depends on the PBH formation redshift \( z_f \), namely \( M \simeq 30 M_\odot [4 \times 10^{11} / (1 + z_f)]^2 \) [8], where \( M_\odot \) is the solar mass \((= 2 \times 10^{33} \text{g})\). Since inflation models [40–46] predict the properties of the primordial curvature perturbations, which determine the mass and abundance of PBHs (see e.g. Refs. [20, 27, 47–49] and references therein), our observational knowledge of the PBHs is important to learn about the physics of the inflationary Universe.

Recently, it has been proposed that the energy-density fraction of PBHs can be constrained by measuring the energy-density spectrum of the stochastic gravitational-wave background (SGWB). First, the SGWB can be produced from an incoherent superposition of GWs emitted from all the coalescing PBH binaries. The null detection of such a SGWB by the first aLIGO observing run [50] has been used to independently constrain \( f_{\text{PBH}} \) [51–54]. For example, Ref. [51]...
obtained the tightest observational constraint on $f_{\text{PBH}}$ in the mass range $1 - 10^2M_\odot$, pushing the existing observational constraints tighter by one order of magnitude. The possibility to detect the SGWB from PBHs, in particular from subsolar-mass PBHs, by upcoming aLIGO observing runs was also predicted [51]. Second, the SGWB is induced from the enhanced primordial curvature perturbations [55–58]. By making use of the semi-analytic calculation of the induced GW spectrum [77, 78], the null detection of such a SGWB by a variety of GW detectors has been used to obtain constraints on the spectral amplitude of primordial curvature perturbations [79–81]. The constraints on the induced SGWB can be recast as the constraints on the abundance of PBHs, and vice versa [70, 82–85].

In this paper, we focus on the small-mass PBHs for $10^{-8}M_\odot \leq M_{\text{PBH}} \leq 1M_\odot$. Correspondingly, we calculate the energy-density fraction of the above two kinds of SGWBs, and report the expected constraints on the energy-density fraction of PBHs from the null detection of the SGWBs by several on-going and planned GW experiments (see details in Ref. [86]), which include Square Kilometre Array (SKA) [87], Laser Interferometer Space Antenna (LISA) [88] and evolved LISA (eLISA) [89], DECi-hertz Interferometer Gravitational wave Observatory (DECIGO) [90] and B-DECIGO [91], Big Bang Observer (BBO) [92], Einstein Telescope (ET) [93], and aLIGO design sensitivity [94]. First, following Ref. [51], we evaluate the energy-density fraction of the SGWB from binary PBH coalescence, by assuming a monochromatic mass distribution of PBHs. This choice of the delta function is reasonable since the mass distribution of PBHs is insensitive to the details of the spectral shape of primordial curvature perturbations especially after taking into account coarse graining within the Hubble horizon and the effects of critical collapse [48]. In addition, the inflation scenario does not favor a significantly extended PBH mass distribution [11]. Second, following Ref. [77], we evaluate the energy-density fraction of the induced SGWB, by assuming a delta function for the power spectrum of primordial curvature perturbations. In principle, the spectrum of the induced SGWB depends on the details of the spectral shape of primordial curvature perturbations. Recently, Ref. [80] found a spread of the SGWB spectrum by studying a log-normal distribution for the power spectrum of primordial curvature perturbations. In this work, the spectral index of the induced SGWB can be regarded as the conservative one.2

The rest of the paper is arranged as follows. In Sec. II, we briefly review the formation of PBHs in the early Universe, given the power spectrum of primordial curvature perturbations. In Sec. III, we evaluate the energy-density fraction of the SGWB from binary PBH coalescence, and use it to obtain expected constraints on $f_{\text{PBH}}$ from a variety of on-going and planned GW detectors. In Sec. IV, we evaluate the induced SGWB from the enhanced primordial curvature perturbations, and obtain the expected constraints on the energy-density fraction of PBHs from SKA, LISA and eLISA. The conclusions and discussions are given in Sec. V.

II. FORMATION OF PRIMORDIAL BLACK HOLES

Given the power spectrum of the primordial curvature perturbations, we can evaluate a probability of the PBH production, the mass function of PBHs and the PBH abundance [20, 27]. In this work we assume that the PBHs are formed in the early Universe which is radiation dominated (RD). First of all, we need to estimate the wavenumber scale $k$ which is related with a given mass scale $M_H$ within the Hubble horizon at the time of horizon re-entry. According to Appendix A, it is represented by

$$
\frac{k}{k_\ast} = 7.49 \times 10^7 \left( \frac{M_\odot}{M_H} \right)^{1/2} \left( \frac{g_{s,\rho}(T(M_H))}{106.75} \right)^{1/4} \left( \frac{g_{s,s}(T(M_H))}{106.75} \right)^{-1/3},
$$

where $k_\ast = 0.05\text{Mpc}^{-1}$. Here we can numerically obtain the temperature at the formation $T(M_H)$ by using Eq. (A6). The effective degrees of freedom of relativistic particles, i.e. $g_{s,\rho}$ and $g_{s,s}$, are precisely calculated for the Standard Model in Ref. [95]. Here we interpolate the tabulated data provided by the associated website 3 to this reference.

The phenomena of critical collapse [11, 96] could describe the formation of PBHs with mass $M$ in the early Universe, depending on the horizon mass $M_H$ and the amplitude of density fluctuation $\delta$. We have the following relation

$$
M = KM_H (\delta - \delta_c)^7,
$$

1 Based on the inflation model, primordial GWs [40, 59] are decoupled with primordial curvature perturbations at the first order. However, the induced GWs can be generated from primordial curvature perturbations at the second order. Whether or not the primordial GWs are detected in the future [60–69], the induced GWs could be sizable and even be larger than the primordial GWs, if the primordial curvature perturbations are significantly enhanced [55–57, 70–76].

2 This is not that simple because the spectral index of the tails of the SGWB is also relevant as well as the width around the peak, and the spectral index depends on the shape of the curvature perturbations. See the discussion around Eq. (58) of Ref. [78]. Anyway, we focus on the delta function case for definiteness.

3 http://member.ipmu.jp/satoshi.shirai/EUS2018
where \( K = 3.3, \gamma = 0.36 \) and \( \delta_c = 0.45 \) are numerical constants \(^4\). The above equation can be inverted to express \( \delta \) in terms of \( M/M_H \), namely, \( \delta = \left( M/(K M_H) \right)^{1/\gamma} + \delta_c \), which is useful in the following calculations.

In the RD Universe, the coarse grained density perturbation is given by

\[
\sigma^2(k) = \int_{-\infty}^{+\infty} d \ln q \ w^2(q/k) \left( \frac{4}{9} \right)^2 \left( \frac{q}{k} \right)^4 T^2(q, \tau = 1/k) P_\zeta(q) ,
\]

where \( w(q/k) = \exp(-q^2/(2k^2)) \) is a Gaussian window function, and \( T(q, \tau) = 3(\sin y - y \cos y)/y^3 \) \((y \equiv q\tau/\sqrt{3})\) is a transfer function (see e.g. Refs. [99, 100] for details). We consider the power spectrum of primordial curvature perturbations \( P_\zeta(k) \) to be a delta function of \( \ln k \), i.e.,

\[
P_\zeta(k) = A \delta(\ln k - \ln k_0) ,
\]

where \( k_0 \) is a given constant wavenumber, and \( A \) is a dimensionless amplitude. By substituting Eq. (4) into Eq. (3), we obtain

\[
\sigma^2(k) = 16A \exp(-1/x^2) \left[ \cos^2 \left( \frac{1}{\sqrt{3}x} \right) + x \left( 3x \sin^2 \left( \frac{1}{\sqrt{3}x} \right) - \sqrt{3} \sin \left( \frac{2}{\sqrt{3}x} \right) \right) \right] ,
\]

where \( x \equiv k/k_0 \) is a dimensionless quantity. We show \( \sigma^2(k)/A \) versus \( k/k_0 \) in a figure at the end of Appendix A.

To convert \( \sigma(k) \) to the mass function of PBHs, by making use of the Press-Schechter formalism \([101]\), we calculate the probability of the PBH production, i.e.,

\[
\beta_{M_H} = \int_{\delta_c}^{\infty} \frac{M}{M_H} P_{M_H} (\delta(M)) d\delta(M) = \int_{-\infty}^{\infty} \frac{M}{M_H} P_{M_H} (\delta(M)) \frac{d\delta(M)}{d \ln M} d \ln M = \int_{-\infty}^{\infty} \frac{3}{2} \bar{\beta}_{M_H}(M) d \ln M ,
\]

which accounts for the fraction of the Hubble volumes that collapse into PBHs when the horizon mass is \( M_H \). \( \bar{\beta}_{M_H}(M) \) is the distribution of the (logarithmic) masses of PBHs resulting after the critical collapse. Here \( P_{M_H}(\delta) \) denotes a Gaussian probability distribution of primordial density perturbations at the given horizon scale corresponding to \( M_H \). It is represented by

\[
P_{M_H}(\delta(M)) = \frac{1}{\sqrt{2\pi \sigma^2(k(M_H))}} \exp \left( -\frac{\delta^2(M)}{2\sigma^2(k(M_H))} \right) ,
\]

where \( \sigma(k(M_H)) \) is computed by making use of Eq. (5), and \( k(M_H) \) is given by Eq. (1). The explicit form of \( \bar{\beta}_{M_H}(M) \) is written to be \([102]\)

\[
\bar{\beta}_{M_H}(M) = \frac{K}{\sqrt{2\pi \gamma \sigma(k(M_H))}} \left( \frac{M}{K M_H} \right)^{1+\frac{\gamma}{2}} \exp \left( -\frac{1}{2\sigma^2(k(M_H))} \left( \delta_c + \left( \frac{M}{K M_H} \right)^{\frac{\gamma}{2}} \right)^2 \right) .
\]

The mass function of PBHs is defined as \( f(M) = \frac{d\bar{\beta}_{PBH}}{d \ln M} \), and the abundance of PBHs in CDM is given by \( f_{PBH} = \int f(M) d \ln (M/M_\odot) \). We obtain the mass function of PBHs as follows (see e.g. Ref. [48])

\[
f(M) = \frac{\Omega_m}{\Omega_{CDM}} \int_{-\infty}^{\infty} \left( \frac{g_{* \rho}(T(M_H))}{g_{* \rho}(T_{eq})} \frac{g_{* s}(T_{eq})}{g_{* s}(T(M_H))} \frac{T(M_H)}{T_{eq}} \right) \bar{\beta}_{M_H}(M) d \ln M_H ,
\]

where \( T_{eq} \) is the temperature of the Universe at the epoch of matter-radiation equality. In Fig. 1, we depict several examples (colored solid) for the mass function \( f(M) \) which is originated from \( P_\zeta(k) \) in Eq. (4). To be specific, we choose a horizon mass to be \( M_H = 10^{-7}M_\odot \) \((i = 0, 1, 2, \ldots, 8)\), each of which determines the value of its own \( k_0 = k_0(M_H) \). Here (1024) is 5.8898, 5.4658, 5.1116, 4.8011, 4.6799, 4.6490, 4.3002, 3.8740 and 3.6813, respectively, so that \( f_{PBH} \) equals the upper limit on \( f(M) \) with the aforementioned values of \( M_H \). For comparison, we plot the existing observational constraint (red dashed) on the PBH mass function. The constraint used here arises from the microlensing observations of Subaru/HSC \([103]\), OGLE \([104]\), EROS-2 \([105]\), MACHO \([106]\), and the caustic crossing \([107]\).

\(^4\) Analytically it is estimated to be \( \delta_c = 0.41 \) \([97]\). In fact, however, they depend on the radial profile of the density perturbations. \([98]\)
III. STOCHASTIC GRAVITATIONAL-WAVE BACKGROUND DUE TO BINARY PRIMORDIAL BLACK HOLE MERGERS

Two different mechanisms have been proposed to form binaries from the PBHs. One scenario assumes that two PBHs could form a binary due to the energy loss via gravitational radiation when they pass by each other accidentally in the late Universe [7, 9]. The other one assumes that two nearby PBHs form a binary due to the tidal force from a third neighboring PBH in the early Universe [8, 108, 109]. Both scenarios are capable of explaining the merger rates of BBHs reported by aLIGO. However, the first one requires the PBHs to contribute most of the CDM, which is disfavored by various observational constraints in the relevant mass range. On the other hand, the second one is still allowed. In this work, we thus adopt the formation scenario of PBH binaries proposed in Ref. [108] and revisited by Refs. [8, 10, 36, 109–116]. In Appendix B we show a brief summary of the formalism for such a scenario.

We calculate the SGWB spectrum produced from the coalescing PBH binaries. In general, the dimensionless energy-density spectrum of the SGWB is defined as \( \Omega_{\text{GW}} = \rho c^{-1}d\rho_{\text{GW}}/d\ln \nu \), where \( \rho_{\text{GW}} \) is the GW energy density, and \( \nu \) is the GW frequency [117]. Knowing the merger rate of PBH binaries in Eq. (B2), according to Ref. [51], we can compute the SGWB energy-density spectrum within the frequency interval \((\nu, \nu + d\nu)\). It is given by

\[
\Omega_{\text{GW}}(\nu) = \frac{\nu}{\rho c} \int_{0}^{\frac{\nu \rho_{\text{BH}}(z)}{1+z}} R_{\text{GW}}(z) \frac{dE_{\text{GW}}(\nu_{s})}{d\nu_{s}} d\nu_{s},
\]

where \( \frac{dE_{\text{GW}}}{d\nu_{s}}(\nu_{s}) \) is the GW energy spectrum of a BBH coalescence (see details in Refs. [118, 119], or a brief summary in Appendix C), \( \nu_{s} \) is the frequency in the source frame and is related to the observed frequency \( \nu \) through \( \nu_{s} = (1+z)\nu \), and \( \nu_{\text{cut}} \) is the cutoff frequency for a given BBH system.

For the PBH binaries for the component masses \( 10^{-i}M_{\odot} \) \((i = 0, 1, 2, ... , 8)\), which correspond to the examples of the PBH mass function in Fig. 1, we plot the corresponding energy-density fractions of the SGWB due to binary PBH coalescence at the existing observational constraints on the PBH abundance in Fig. 2. The color coding is the same as that in Fig. 1. For comparison, we depict the sensitivity curves of several GW experiments (colored

\[5\] In this section, we use the revised formalism in Ref. [20], instead of the original one in Ref. [8].

\[6\] Sometimes, only the amplitude spectral density \( S_{n}(f) \) is shown for a given gravitational-wave detector. We have \( \sqrt{S_{n}(f)} = h_{n}(f)^{\nu - 1/2} \), which has the unit of Hz\(^{-1/2}\), and \( h_{n} \) is the noise amplitude. The sensitivity to the SGWB energy density is related with \( S_{n}(f) \) by \( \Omega_{\text{GW,n}}(f) = 3.132 \times 10^{35}h^{2}(f/\text{Hz})^{3} \sqrt{S_{n}(f)/\text{Hz}^{-1/2}}^{2} \) [120, 121]. The reduced Hubble constant is \( h = 0.678 \) in this paper.
FIG. 2: Energy-density spectrum (colored solid) of the SGWB due to binary PBH coalescence which is just allowed by the existing observational constraints on the PBH abundance. The SGWB spectra with the cutoff frequencies from right to left correspond to the peaks from left to right in Fig. 1 (same colors). The sensitivity curves (colored dashed/dotted) of the GW detectors are also plotted for comparison.

FIG. 3: Expected constraints on the PBH abundance from the null detection of the SGWB by LISA (orange solid), B-DECIGO (green dashed), DECIGO (green solid), BBO (blue solid), ET (cyan solid), and aLIGO (purple dashed). The present existing constraint (red dashed) is plotted for comparison.

dashed/dotted curves), which include pulsar timing array (SKA [87]), space-based GW interferometers (LISA [88] and eLISA [89], DECIGO [90] and B-DECIGO [91], BBO [92]), third-generation ground-based GW interferometer (ET [93]) and second-generation ground-based GW interferometer (aLIGO [94]). If the spectrum predicted in a model intersects the sensitivity curve of a given experiment, the expected signal-to-noise ratio (SNR) is equal to or greater than unity, which means a possible detection of such a spectrum by this experiment.

Null detection of the SGWB by the given future or on-going GW experiment can place an upper bound on the magnitude of the energy-density fraction of the SGWB at a given frequency band, and can be further recast to constrain the maximum PBH abundance. From Fig. 2, all the GW experiments except SKA and eLISA have possible contributions to improve the existing observational constraints on the PBH abundance, since their sensitivity curves intersect some spectra. Therefore, by regarding the sensitivity curves of all these experiments as upper bounds on the SGWB spectrum, we evaluate the expected upper limits on the PBH abundance from these experiments. We depict
our results in Fig. 3. Here we omit SKA and eLISA since they do not improve the existing observational constraints.

Our results are as follows. Both LISA and aLIGO will give us similar constraints in future. It is notable that this expected limit from aLIGO is surely stronger than the current one which was reported recently by Ref. [36]. Both ET and B-DECIGO also have similar constraints on the abundances. All the above four experiments are expected to improve the existing observational constraints on the subsolar-mass PBHs. However, both DECIGO and BBO are expected to significantly improve the existing constraints over the mass range $\mathcal{O}(10^{-6}) \leq M/M_\odot \leq \mathcal{O}(10^0)$.

IV. STOCHASTIC GRAVITATIONAL-WAVE BACKGROUND INDUCED BY PRIMORDIAL CURVATURE PERTURBATIONS

The SGWB can be also induced by the enhanced primordial curvature perturbations via the scalar-tensor mode coupling in the second-order perturbation theory [56]. In Appendix D, we show a brief summary of the evaluations of the induced SGWB spectrum. For details, see Ref. [77] and references therein. In the following, we will use Appendix D to calculate the energy-density spectrum of the induced SGWB, given the form of $P_\zeta(k)$ in Eq. (4).

According to Eqs. (D1)–(D3), we obtain the dimensionless energy-density spectrum of the induced SGWB as

$$
\Omega_{\text{IGW}} \left( \nu = \frac{k}{2\pi} \right) = \Omega_{r,0} \left( \frac{g_s(T(k))}{g_s(T_{eq})} \right) \left( \frac{g_{s,s}(T(k))}{g_{s,s}(T_{eq})} \right)^{-4/3} \times \left[ \pi^2 \left( 3\tilde{k}^2 - 2 \right)^2 \Theta(2 - \sqrt{3}\tilde{k}) + \left( 4 + \left( 3\tilde{k}^2 - 2 \right) \ln \left| 1 - \frac{4}{3\tilde{k}^2} \right| \right)^2 \right] \Theta(2 - \tilde{k}),
$$

where $\nu = k/2\pi$ denotes the frequency of GW, and the dimensionless wavenumber $\tilde{k} = k/k_0$ is introduced for simplicity. Based on Appendix A, cosmic temperature $T$ can be numerically related with $M_H$ and $k$, and then with $\nu$. Here $\Theta(x)$ denotes the Heaviside theta function with variable $x$.

**FIG. 4:** Energy-density spectrum of the SGWB nonlinearly induced by the primordial curvature perturbations. The SGWB spectra (colored solid) with the peaks from right to left correspond to the mass functions with the peaks from left to right in Fig. 1 (same colors).

Similarly to Fig. 2, we plot the energy-density fractions of the induced SGWB due to the enhanced primordial curvature perturbations in Fig. 4. Both $A$ and $k_0$ are chosen as those in Sec. II. The same color coding is used as in Fig. 1. The double-peak structures arise from the property of the delta function for $P_\zeta(k)$ in Eq. (4). For a broader distribution for $P_\zeta(k)$, e.g., a log-normal distribution in Ref. [80], one could find a spread of the SGWB spectrum. Therefore, our discussions in the next two paragraphs could be regarded as conservative.

In Fig. 5, besides the energy-density spectra of the induced SGWB (colored solid, same as Fig. 4), we depict the sensitivity curves of SKA [87] (red dashed), LISA [88] (orange dashed) and eLISA [89] (orange dotted) for comparison.
FIG. 5: Similarly to Fig. 4, we plot the energy-density spectrum of the induced SGWB (colored solid), but the right-handed peak is conservatively dropped. We depict the sensitivity curves of SKA (red dashed), LISA (orange dashed) and eLISA (orange dotted) for comparison.

For a given spectrum of the induced SGWB, we conservatively drop the right-handed peak since the integral area under this peak is much smaller than the left-handed one and also since such a spiky structure exists only for source spectra with a tiny width. Similarly to the discussions in last section, if a model-predicting spectrum intersects the sensitivity curve of a given experiment, it is possible to measure such a spectrum by this experiment. In such a case, both SKA and LISA are expected to exclude most of the parameter space, or equivalently improve the existing observational constraints on the PBH abundance significantly. By contrast, eLISA can bring relatively few improvement.

Assuming the null detection of the induced SGWB from the enhanced primordial curvature perturbations, similarly to Fig. 3, we plot the expected constraints on the PBH abundance from SKA (red shaded), LISA (orange shaded) and eLISA (blue shaded) in Fig. 6. The shaded regions mean the excluded parts of the parameter space by these three experiments. In fact, here we first obtain the constraints on $A$ from the induced SGWB, and then recast them as the upper limits on $f_{\text{PBH}}$ according to the formulae in Sec. II.
V. CONCLUSIONS

It has been known that PBHs can form binaries in the early Universe, and a PBH binary can merge to a new heavier BH due to the energy loss via gravitational radiation. Based on Ref. [8], the merger rate of PBH binaries depends on the abundance and mass of PBHs. Given the existing constraints on the mass function of PBHs, following Ref. [51], we have evaluated the energy-density spectra of SGWBs which arise from coalescences of PBH binaries with component masses $10^{-i}M_\odot$ ($i = 0, 1, 2, ..., 8$). From Fig. 2, we found that some of them intersect the sensitivity curves of several future GW experiments. This means that the existing limits can be improved by these experiments in the future if these experiments do not detect the SGWB. By making use of these sensitivity curves as upper limits on the SGWB energy-density fraction, we have evaluated the expected upper limits on the abundance of PBHs, and shown our results in Fig. 3. In particular, both DECIGO and BBO are expected to significantly improve the existing limits over the mass range $10^{-6}M_\odot - 10^{0}M_\odot$.

The generation of PBHs in the early Universe requires large amplitudes of the primordial curvature perturbations, which can always induce the SGWB. By taking into account the existing constraints on the mass function of PBHs and making use of the semi-analytic formula in Ref. [77], we have calculated the energy-density spectrum of the induced SGWB, and shown our results in Fig. 4. We find several intersections between the induced SGWB spectra and the sensitivity curves of SKA, LISA and eLISA in Fig. 5. This implies that these experiments can improve the existing upper limits on the mass function of PBHs in the future if they claim the null detection of the induced SGWB energy-density fraction. In this case, the three shaded regions in Fig. 6 will be excluded by SKA, LISA and eLISA, respectively.

![FIG. 7: Expected constraints on the PBH abundance versus the PBH mass from the null detection of the two kinds of SGWBs. The existing observational constraint (red dashed) is plotted for comparison.](image_url)

Finally, we can combine the results in Fig. 3 with Fig. 6 to obtain Fig. 7. Generally speaking, the slopes of the upper bounds (i.e., boundaries of shaded regions) from the induced SGWB are significantly sharper than those (i.e., colored curves) from the SGWB due to the coalescing PBH binaries. This property can be easily understood as follows. On the one hand, we directly constrained the magnitude of $f_{PBH}$ by calculating the SGWB from the coalescing PBH binaries. The detection of such a SGWB requires a significant amount of PBH binaries in the Universe. This implies that the GW detectors can probe the enhanced primordial curvature perturbations only if $A \sim O(0.1)$. When $A \ll O(0.1)$, there would be so few PBHs in the Universe that the thresholds of GW detectors are not triggered. On the other hand, by detecting the induced SGWB, we directly obtained the constraints on $A$, which were recast as the indirect constraints on $f_{PBH}$. In fact, by detecting the induced SGWB, the GW detectors can probe the primordial curvature perturbations of arbitrary amplitudes within their sensitivities. Since the induced SGWB spectrum is proportional to $A^2$ while $f_{PBH}$ is exponentially sensitive to $A$, we obtained the sharper slopes for the upper bounds from the induced SGWB than those from the SGWB due to coalescing PBH binaries in Fig. 7. Thus, the constraints on $f_{PBH}$ from the SGWB induced by the curvature perturbations are stronger than those from the SGWB whose origin is merger events except for a narrow gap between $10^{-5}M_\odot$ and $10^{-4}M_\odot$ corresponding to the relatively weak observational sensitivity around about $10^{-5}$Hz. Nevertheless, both types of the SGWB are complementary and useful for the consistency check.
of the PBH hypothesis since those two types of the SGWB have their own individual features in the spectra and are probed by different observations which are supposed to measure GWs at different frequency bands.

Appendix A: Relation between $k$ and $M_H$ in the radiation dominated Universe

During the radiation dominated (RD) era of the Universe, the relation between the wavenumber $k$ and the horizon mass $M_H$ is obtained as follows. By definition, we have

$$k = a(M_H)H(M_H).$$  \hspace{1cm} (A1)

The value of the scale factor $a(M_H)$, when the mode corresponding to $M_H$ re-enters the Hubble horizon, is obtained by using the entropy conservation to be

$$a(M_H) = a_0(=1) \left( \frac{g_{*,s}(T_0)}{g_{*,s}(T(M_H))} \right)^{1/3} \frac{T_0}{T(M_H)},$$  \hspace{1cm} (A2)

where $T_0 = 2.725K$ denotes the present temperature of the CMB, and the temperature $T(M_H)$ is given by the Friedmann equation, i.e.,

$$3H^2(M_H)M_G^2 = \rho \approx \rho_{\text{rad}} = \frac{\pi^2 g_{*,\rho}(T(M_H))}{30} T^4(M_H),$$  \hspace{1cm} (A3)

where $M_G = M_P/\sqrt{8\pi}$ is the reduced Planck mass. The relation between the horizon mass $M_H$ and the Hubble radius $H^{-1}$ is given by

$$M_H = \frac{4\pi}{3} (H(M_H))^{-3} \rho.$$  \hspace{1cm} (A4)

Combining Eq. (A4) with the left equality of Eq. (A3), we have the following formula between $H$ and $M_H$, i.e.,

$$H(M_H) = 4\pi \frac{M_G^2}{M_H}.$$  \hspace{1cm} (A5)

By combining Eq. (A5) with the right equality of Eq. (A3), we thus obtain a relation between $M_H$ and $T$, i.e.,

$$M_H = 12 \left( \frac{10}{g_{*,\rho}(T)} \right)^{1/2} \frac{M_G^3}{T^2}.$$  \hspace{1cm} (A6)

Combining Eqs. (A1), (A2), (A5) and (A6) together, we obtain

$$\frac{k}{k_*} = 7.49 \times 10^7 \left( \frac{M_\odot}{M_H} \right)^{1/2} \left( \frac{g_{*,\rho}(T(M_H))}{106.75} \right)^{1/4} \left( \frac{g_{*,s}(T(M_H))}{106.75} \right)^{-1/3},$$  \hspace{1cm} (A7)

where $M_\odot$ denotes the solar mass and $k_* = 0.05\text{Mpc}^{-1}$.

In the following, we depict Fig. 8 to show $\sigma^2(k)/A$ versus $k/k_0$. In the wavenumber space, the peak of the coarse grained perturbations shifts from the original peak $k_0$. Numerically, the shifted peak is obtained as $k = 0.730715k_0$.

$$\frac{k_{\text{peak of PBHs}}(\text{peak of primordial curvature perturbations})}{k_{\text{peak of PBHs}}} = 0.730715.$$  \hspace{1cm} (A8)

In our example by assuming $P_\zeta(k)$ to be the delta function, the wavenumber in the denominator is nothing but $k_0$. When a PBH forms, the shorter scales had already experienced the radiation pressure and have been smoothened. Therefore, the PBH mass scale corresponds to the coarse grained perturbation scale. In other words, $k$ in Eqs. (1) and (A7) should be the one appearing in the numerator of the left-hand side of Eq. (A8).
Appendix B: Formalism for the merger rate of PBH binaries

Given the fraction of PBHs in CDM, namely \( f_{PBH} \), for a fixed PBH mass \( M \), the probability that a PBH binary coalesces within the cosmic time interval \((t, t + dt)\) is given by (see e.g. Refs. [8, 20] for details)

\[
dP_t = \begin{cases} 
\frac{3}{58} \left[ -\left( \frac{t}{t_0} \right)^{\frac{8}{3}} + \left( \frac{t}{t_0} \right)^{\frac{2}{3}} \right] \frac{dt}{t} & \text{for } t < t_c \\
\frac{3}{58} \left[ 1 + \left( \frac{t}{t_0} \right)^{\frac{8}{3}} \right] \left( \frac{4\pi f_{PBH}}{3} \right)^{-\frac{29}{3}} \frac{dt}{t} & \text{for } t \geq t_c,
\end{cases}
\] (B1)

where we define \( t_0 = (3/170) \{ \bar{x}^4/[[GM]^{3} (4\pi f_{PBH}/3)^{4}] \} \) and \( t_c = t_0 (4\pi f_{PBH}/3)^{37/3} \), and \( \bar{x} = [3M/(4\pi \rho_{PBH, eq})]^{1/3} \) is the physical mean separation of PBHs at the epoch of matter-radiation equality. Here \( \rho_{PBH, eq} \) is the energy density of the PBHs at the epoch of matter-radiation equality. Multiplying \( dP_t/dt \) by the present average number density of PBHs, one can obtain the merger rate of PBH binaries as

\[
R_{PBH}(z) = \left( f_{PBH} \Omega_{CDM} \rho_c / M \right) \frac{dP_t}{dt}.
\] (B2)

The redshift \( z \) is related to the cosmic time \( t \) through \( t = \int_{z}^{\infty} dz'/((1 + z')H(z')) \), where \( H(z) = H_0[\Omega_{r,0}(1 + z)^4 + \Omega_{m,0}(1 + z)^3 + \Omega_{\Lambda}]^{1/2} \) is Hubble parameter at redshift \( z \). The quantities \( \Omega_{r,0} \) and \( \Omega_{m,0} \) denote the present energy-density fractions of radiations and non-relativistic matter, respectively. The present energy-density fraction of dark energy is derived as \( \Omega_{\Lambda} = 1 - \Omega_{r,0} - \Omega_{m,0} \). Here \( \rho_c = 3H_0^2 M_0^2 \) is the critical energy density of the Universe. Throughout this paper, we adopt the \( \Lambda \)CDM model with cosmological parameters measured by Planck satellite [122].

---

7 As was discussed in the Introduction, we use a monochromatic mass distribution of PBHs as a reasonable approximation here. Therefore, we use the PBH abundance \( f_{PBH} \) instead of the PBH mass function \( f(M) \).
Appendix C: Energy spectrum of gravitational waves

In the non-spinning limit, the inspiral-merger-ringdown energy spectrum for a BBH coalescence takes the following form [118, 119]

\[
\frac{dE_{GW}}{d\nu_s}(\nu_s) = \frac{(G\eta)^{2/3} M_s^{5/3}}{3} \begin{cases} 
\nu_s^{-1/3} & \text{for } \nu_s < \nu_1 \\
\nu_1 \nu_s^{-2/3} & \text{for } \nu_1 < \nu_s < \nu_2 \\
\nu_2 & \text{for } \nu_2 < \nu_s < \nu_3 \\
0 & \text{for } \nu_3 < \nu_s
\end{cases}
\]  

(C1)

where \(\nu_s\) is a GW frequency in the source frame, \(\nu_1\) and \(\nu_2\) are two normalization constants that make the spectrum to be continuous. The parameters \(\nu_i\) (\(i = 1, 2, 3\)) and \(\sigma\) can be expressed in terms of \(M_s\) and \(\eta\) as follows

\[
\begin{align*}
\pi M_l \nu_1 &= (1 - 4.455 + 3.521) + 0.6437\eta - 0.05822\eta^2 - 7.092\eta^3 \\
\pi M_l \nu_2 &= (1 - 0.63) / 2 + 0.1469\eta - 0.0249\eta^2 + 2.325\eta^3 \\
\pi M_l \sigma &= (1 - 0.63) / 4 - 0.4098\eta + 1.829\eta^2 - 2.87\eta^3 \\
\pi M_l \nu_3 &= 0.3236 - 0.1331\eta - 0.2714\eta^2 + 4.922\eta^3
\end{align*}
\]  

(C2) (C3) (C4) (C5)

which can be found in Table 1 of Ref. [119]. Here \(M_c\) is the chirp mass, i.e., \(M_c^{5/3} = m_1 m_2 (m_1 + m_2)^{-1/3}\), and \(M_l = m_1 + m_2\) is the total mass. The symmetric mass ratio is defined by \(\eta = m_1 m_2 (m_1 + m_2)^{-2}\), which gives 0.25 in this work, since we assume the monochromatic mass of PBHs. The cutoff frequency is given to be \(\nu_{cut} = \nu_3\).

Appendix D: Curvature-induced gravitational waves in a nutshell

We briefly summarize the semi-analytic calculation of the SGWB spectrum induced in the RD era from the non-linear (tensor-scalar-scalar) mode coupling. The details are described in Ref. [77] and references therein. The energy-density fraction of the induced SGWB is given by

\[
\Omega_{GW}(k)|_{today} = \Omega_{c,0} \left( \frac{g_{s,\rho}(T)}{g_{s,s}(T_{eq})} \right) \left( \frac{g_{s,s}(T_{eq})}{g_{s,\rho}(T_{eq})} \right)^{-4/3} \left( \frac{k}{aH} \right)^2 \int P_h(\tau, k) \, d\nu, \quad \text{(D1)}
\]

where cosmic temperature \(T = T(M_H(k))\) with the horizon mass \(M_H(k)\), \(aH\) and conformal time \(\tau\) are to be evaluated at (a time somewhat after) the horizon entry of the relevant mode (when the \(\Omega_{GW}\) has reached a temporary asymptotic value). In fact, \(T(M_H(k))\) can be numerically evaluated by combining Eq. (A6) with Eq. (A7). The last two factors in the above formula are given by

\[
\left( \frac{k}{aH} \right)^2 P_h(\tau, k) = 4 \int_0^\infty dv \int_{|1-v|}^{1+v} du \left[ 4u^2 - (1 + v^2 - u^2)^2 \right] \left( k\tau \right)^2 \mathcal{T}^2(v, u, k\tau \gg 1) P_\zeta(kv) P_\zeta(ku). \quad \text{(D2)}
\]

In the above equation, we have

\[
(k\tau)^2 \mathcal{T}^2(v, u, k\tau \gg 1) = \frac{1}{2} \left( \frac{3(u^2 + v^2 - 3)^2}{4uv^3} \right) \left( -4uv + (u^2 + v^2 - 3) \ln \left[ 3 + (u^2 - v^2)^2 \right] \right) \quad \text{(D3)}
\]

Then, we combine the above three equations to compute the energy-density spectrum of the induced SGWB in this work. In case of the delta function source (Eq. (4)), the integral is easily calculated to obtain Eq. (11).
