We study the emerging large-scale structures in networks subject to selective pressures that simultaneously drive towards higher modularity and robustness against random failures. We construct maximum-entropy null models that isolate the effects of the joint optimization on the network structure from any kind of evolutionary dynamics. Our analysis reveals a rich phase diagram of optimized structures, composed of many combinations of modular, core-periphery and bipartite patterns. Furthermore, we observe parameter regions where the simultaneous optimization can be either synergistic or antagonistic, with the improvement of one criterion directly aiding or hindering the other, respectively. Our results show how interactions between different selective pressures can be pivotal in determining the emerging network structure, and that these interactions can be captured by simple network models.

I. INTRODUCTION
The observed large-scale structure of network systems emerges as the outcome of various kinds of generative processes, which tend to vary substantially depending on their empirical context. Nevertheless, in a large class of network formation mechanisms, in particular in biological, engineering and technological settings, an important driving force is the fitness to a specific purpose [1–6], e.g. the survival of an individual, the efficiency of a production line, or the capacity of a transportation system. This results in a selective pressure towards particular network structures, depending on the kind of fitness that is desired. However, in realistic scenarios, selective pressures occur in combination with other kinds of dynamical rules, exogenous constraints and historical artefacts. Furthermore, a given system may be subject to multiple selective pressures at the same time, e.g. it may need to run efficiently while being simultaneously robust to errors or damage. Since very seldom do we get to observe any given process of formation in detail, we are forced to disentangle these different driving forces from each other based only on the structural patterns they produce.

In this work, we contribute to the disentangling effort by constructing null models of optimized networks [7]. These models correspond to network ensembles that possess a pre-specified level of fitness, but otherwise are maximally random. By investigating the emerging structural features in these models, we are able to understand the inherent effect a particular kind of fitness criterion has on the structure of the network, without the interference of any other kind of constraint. We can also combine multiple fitness criteria together to determine how they interact with each other in determining the preferred network structure. This gives us a controlled platform to delineate the effects of different kinds of selective pressures on network structure in a principled manner.

In the following we will employ this approach to investigate two central properties of networked systems, namely the robustness of a network against the random failure of its components [8], and its modularity [9], characterized by the existence of groups of nodes that are more connected among themselves than with the rest of the network. Robustness to failure is believed to play a key role in infrastructure [10] as well as technological networks such as the internet [11], but also on biological systems [12]. Modularity, on the other hand, has been associated with the adaptability of biological networks [6], and is a necessary ingredient for the scheduling of interdependent processes with minimal amount of communication [13]. By enforcing these two optimization criteria simultaneously, we analyse which large-scale network structures are most likely to emerge as a result of their interaction. Our main result is the identification of a series of phase transitions at which the optimal structure of the network changes in response to the varying selective pressures. We also identify regions in the parameter space where the interplay between the selective pressures gives rise to synergistic effects, i.e. one kind of fitness pressure contributes to the second, such that it becomes easier to optimize for both at once, as well as antagonistic effects, where both optimizations compete against each other.

The work is divided as follows. We begin in Sec. [11] by introducing our modelling framework. In Sec. [11] we apply our framework to network ensembles subject to varying degrees of selective pressures in favor of robust-
ness against random failures as well as modularity. We begin by considering each fitness criteria separately and subsequently combine them to analyze the effects that their interaction has on the emerging network structures. Finally, in Sec. [V] we draw our conclusions.

II. NULL MODELS OF OPTIMIZED MODULAR NETWORKS

We approach the problem of characterizing network structures via generative models. This means that instead of describing individual networks, we are interested in formulating network ensembles, such that the probability of observing a given network is associated with its particular fitness value, given a predefined fitness criterion. There are many ways to address this problem, but here we constrain ourselves to networks that exhibit modular structure, i.e. the nodes are divided into groups, which share a similar role in the network structure. More specifically, we consider networks that are generated from the stochastic block model (SBM) [14–16], where N nodes are divided into B groups, such that to each node i is given a group membership label $b_i \in \{1, \ldots, B\}$, and an edge between a node in group r and another in group s exists with probability $p_{rs}$. This yields a network ensemble where a network $A$ occurs with probability

$$P(A | b, p) = \prod_{i<j} p_{b_i b_j}^{A_{ij}} (1-p_{b_i b_j})^{1-A_{ij}},$$

(1)

where $A_{ij} = 1$ if an edge exists between nodes $(i, j)$, or $A_{ij} = 0$ otherwise. Although this is just one of a large set of possible network ensembles, the SBM is capable of capturing arbitrary mixing patterns between groups by appropriate choices of the matrix $p$, and if the number of groups is increased it can account for arbitrarily elaborate network structures [17]. In fact, setting $B = N$ means that the probability of each edge can be individually controlled, although we will constrain ourselves to the situation where $B \ll N$ and the network is composed of a relatively small number of modules. Although this does not give us the full breadth of all possible network structures — in particular we lack the ability of describing the details of the network structure at a local level, e.g. by stipulating desired propensities of observing triangles or other small subgraphs — as we will see, this is a sufficiently flexible framework to express the kind of null models we have in mind.

For a given arbitrary fitness function $R(A)$, which maps a network to a scalar fitness value, the average fitness over the SBM ensemble is then given by

$$R(b, p) = \sum_A R(A) P(A | b, p).$$

(2)

Based on such a function, we could in principle proceed by finding the SBM parameters $b$ and $p$ such that the mean fitness $R(b, p)$ is maximized, and in this way finding how a fitness criterion favors certain patterns of network structures. However, this kind of optimization problem is ill-defined in the general case, as many parameter choices yield the same optimal fitness value. Therefore, we formulate our question differently. Instead of optimizing the mean fitness $R(b, p)$, we impose its value as a predetermined parameter, and we select the SBM parameters that yield the most random network ensemble, and therefore is the most agnostic about the unimportant properties of the network structure. More formally, this means we employ the principle of maximum entropy [13], such that for any imposed fitness value $R(b, p) = R^*$, the choice of the model parameters $b$ and $p$ from all those that fulfill this constraint is the one that maximizes the ensemble entropy [19].

$$\Sigma(b, p) = -\sum_A P(A | b, p) \ln P(A | b, p).$$

(3)

In this way, if we specify a set of fitness functions $\{R_i(b, p)\}$ and their imposed set of values $\{R^*_i\}$, we are interested in the following constrained optimization problem

$$\hat{b}, \hat{p} = \arg\max_{b, p} \Sigma(b, p), \text{ subject to } R_i(b, p) = R^*_i \forall i.$$  

(4)

The SBM parameters obtained in this way can be interpreted as null models of networks, which contain only the most essential ingredients to achieve the pre-specified values of fitness, and otherwise are maximally random. The imposed fitness values themselves can be increased arbitrarily, to achieve any level of optimized structures, as we will show.

We can compute the entropy of the SBM ensemble by substituting Eq. (1) into Eq. (3) which yields [20]

$$\Sigma(b, p) = \sum_{r<s} n_r n_s H_b(p_{rs}) + \sum_r \frac{n_r(n_r-1)}{2} H_b(p_{rr}),$$

(5)

where $n_r = \sum_i \delta_{b_i r}$ is the number of nodes in group $r$, and $H_b(x) = -x \ln x + (1-x) \ln (1-x)$ is the binary entropy function. This can be further simplified if we take into account that most networks in the real world are sparse with $p_{rs} = O(1/N)$, so that using $H_b(x) = -x \ln x + x + O(x^2)$, and taking the limit $N \gg 1$ we obtain

$$\Sigma(b, p) = -\frac{1}{2} \sum_{r<s} n_r n_s \left( p_{rs} \ln p_{rs} - p_{rs} \right).$$

(6)

For some choices of fitness functions, arbitrarily high fitness values can be obtained simply by increasing the network density. In order to differentiate between the effect of increased density and favored mixing patterns, we will take the average degree $(k) = \sum_{rs} n_r n_s p_{rs}/N$ as an external parameter not subject to optimization. With this in mind, it will be useful for our calculations to use the
finding the saddle points of the Lagrangian function.

\[ \omega_r = \frac{n_r}{N}, \quad m_{rs} = \frac{n_r n_s d_{rs}}{N(k)}, \]

Note that the above implies the normalization \( \sum_r \omega_r = 1 \) and \( \sum_{rs} m_{rs} = 1 \). Given this choice, the ensemble entropy can be written as

\[ \Sigma(\omega, m) = -\frac{(k)N}{2} \sum_{rs} m_{rs} \ln \frac{m_{rs}}{\omega_r \omega_s} + \frac{(k)N}{2} \]  

Note that we no longer reference the actual partition \( b \) itself, but rather the fraction of nodes \( \omega_r \) that belong to a given group \( r \), since these are the relevant macroscopic quantities as \( N \gg 1 \).

Based on the above model parametrization, we can perform the constrained optimization of Eq. [3] by employing the method of Lagrange multipliers, which involves finding the saddle points of the Lagrangian function

\[ \Lambda(\omega, m, \beta) = \Sigma(\omega, m) + \sum_i \beta_i [R_i(\omega, m) - R^*_i], \]

where \( \beta_i \) are the Lagrange multipliers that enforce each constraint. This means we need to find \( \omega, m \), and \( \beta \) such that the gradient of \( \Lambda \) is zero, i.e. \( \partial \Lambda(\omega, m, \beta)/\partial \omega_r = \partial \Lambda(\omega, m, \beta)/\partial m_{rs} = \partial \Lambda(\omega, m, \beta)/\partial \beta_i = 0 \). Note that the last derivative yields simply the equation \( R_i(\omega, m) = R^*_i \), which means that the problem of fixing \( R^*_i \) and finding \( \omega, m, \beta \) is equivalent to first taking \( \beta \) as fixed parameters and minimizing the function

\[ F(\omega, m) = -\sum_i \beta_i R_i(\omega, m) - \Sigma(\omega, m), \]

with respect to \( \omega \) and \( m \) alone and then varying \( \beta \) until we obtain \( R_i(\omega, m) = R^*_i \).

The above formulation puts us in a standard setting in equilibrium statistical physics, as the function \( F(\omega, m) \) can be interpreted as the free energy of the network ensemble where the sum \(-\sum_i \beta_i R_i(\omega, m)\) plays the role of the mean energy. Following this analogy, the values of \( \beta_i \) play the role of inverse temperatures, or perhaps more appropriately to our setting, selective pressures, which if increased cause the corresponding energy functions to decrease (and thus the fitness values to increase), and thus settling on a particular balance between energy and entropy.

To summarize, our protocol to generate null network models is as follows:

1. We establish a set of fitness functions \( \{ R_i(\omega, m) \} \).
2. Given a choice of selective pressures \( \{ \beta_i \} \) we find the parameters \( \omega, m \) which minimize the free energy \( F(\omega, m) \) of Eq. [10]
3. We vary the values \( \{ \beta_i \} \) to investigate the trade-off between competing fitness functions as well as entropy.

The constrained optimization of step 2 is the most central part of our approach. Although it is straightforward to compute the gradient of the entropy \( \Sigma(\omega, m) \) analytically, in the general case this will not be possible for arbitrary fitness functions \( R_i(\omega, m) \), and even when it is, setting the gradient of \( F(\omega, m) \) to zero usually just yields an implicit system of nonlinear equations that cannot be solved in closed form. Therefore, in the following we will proceed by performing the minimization numerically, via the L-BFGS-B conjugate gradient descent algorithm [21], using automatic differentiation [22] whenever the gradient cannot be obtained in closed form. As a final implementation note, the used algorithms require us to convert step 2 into an unbounded optimization problem, which we do via a simple exchange of variables given by

\[ \omega_r = e^{\mu_r}, \quad m_{rs} = e^{\nu_{rs}}, \]

with \( \mu_r \in [-\infty, \infty] \) and \( \nu_{rs} \in [-\infty, \infty] \), which keep both \( \omega_r \) an \( m_{rs} \) bounded in the range \([0, 1]\), and enforce normalization.

### III. FITNESS CRITERIA

We consider two kinds of fitness criteria, namely the robustness against random failures, and modularity. We begin by considering the criteria in isolation, and we follow by combining them simultaneously.

#### A. Robustness against random failures

We consider a situation where a random fraction \( 1 - \phi \) of the edges are removed from the network, and we measure the fraction \( S \) of nodes that remain connected afterwards, forming a giant connected component [23]. Following Ref. [7], we can compute this quantity for the SBM by first defining \( u_\tau \) to be the probability that a node in group \( r \) does not belong to the giant component via one of its neighbors, which can be obtained by solving the set of equations

\[ u_\tau = 1 - \phi + \phi \sum_s m_{rs} f'_s(u_s), \]

where \( m_r = \sum_s m_{rs} \) and \( f'_s(z) = f'_s(z)/f'_s(1) \) is the generating function of the excess degree distribution of nodes belonging to group \( r \), defined in terms of the corresponding degree distribution generating function \( f'_0(z) \) given by

\[ f'_0(z) = \sum_k p^*_k z^k \]

where \( p^*_k \) is the fraction of nodes in group \( r \) that have degree \( k \), which for the SBM is a Poisson distribution with mean \( \kappa_r = \langle k \rangle m_r/\omega_r \), which means we have

\[ f'_0(z) = f'_1(z) = f'(z) = e^{\kappa_r(z-1)}. \]
After solving Eq. [12], which can be done simply by repeated iteration from a starting point $u_r < 1$ until a desired convergence criterion, we can finally obtain $S$ via

$$S = 1 - \sum_r \omega_r f_r(u_r).$$

(15)

For any given SBM, the behavior of $S$ as a function of the fraction $\phi$ of edges that are not removed is that we have $S = 0$ for $\phi \in [0, \phi^*]$, where $\phi^*$ is a critical value, so that for $\phi > \phi^*$ we have a positive fraction of connected nodes $S > 0$ that increases continuously [7].

If we now consider the fitness function $R(\omega, m) = S(\omega, m)$, our resulting free energy becomes

$$F(\omega, m) = -\beta_S S(\omega, m) - \Sigma(\omega, m).$$

(16)

By minimizing the above function we find null network models that are robust against random failures, with the robustness increasing for higher $\beta_S$ values.

In Fig. 1 we show the properties of the obtained models for $(k) = 5$ and $B = 2$ groups. As $\beta_S$ increases, the network ensemble undergoes two abrupt transitions, where the structure first changes from fully random (I) to a core-periphery structure (II), and finally to an asymmetric bipartite structure (III). The core-periphery structure corresponds to a smaller and denser set of “core” nodes which are connected among themselves, and a larger and sparser set of “periphery” nodes which connect mostly to the core nodes, and not among themselves. The asymmetric bipartite structure is similar to the core-periphery pattern, but the “core” nodes no longer preferentially connect to themselves, instead they predominantly connect to the periphery nodes, although they remain a smaller and denser set. An illustration of these structures can be seen in Fig. 2, where we show network samples from the obtained ensembles. In Figs. 3 and 4 we also show the size and density of the two groups as a function of the edge dilution probability $\phi$.

It is easy to understand why a core-periphery structure increases the robustness to random edge removal: the core group corresponds to a denser subgraph which remains connected with a large probability after the removal of a given fraction of edges, and the peripheral nodes benefit directly from this by connecting directly to the core, rather than among themselves. What is perhaps more surprising is the eventual onset of the bipartite structure, at which point the core group becomes so dense that its nodes tend to remain in the giant component even if they are not connected preferentially among themselves, which would incur a large entropy cost for no significant additional benefit, but instead connect mostly to periphery nodes. The latter group tends to remain connected since its nodes tend to receive multiple connections to the denser core nodes. (Similar structures to the core-periphery one encountered here were also seen in similar setups where the robustness was integrated over all possible dilution values $\phi$ [7, 24] as well different ones.

Figure 1. Relative size of the giant component $S$ as a function of the selective pressure for robustness to damage $\beta_S$ for different values of the edge dilution probability $\phi$. The dashed vertical lines indicate the value $\beta_S = \beta^*$ at which we observe a transition from a random structure to a core-periphery one. The solid vertical lines indicate the value $\beta_S = \tilde{\beta}$ at which the network structure transitions from a core-periphery to a bipartite pattern. The optimized network structures are shown schematically in the insets, where each group corresponds to one of the groups of our model.

Figure 2. Ensemble samples depicting the typical evolution of the core-periphery structure as a function of the selective pressure $\beta_S$. (a) When the core-periphery structure first appears, it is composed of a small high-degree core. (b) As $\beta_S$ increases, the size of the core group becomes larger. (c) Before eventually transitioning to a bipartite structure.
Figure 3. Fraction of nodes and average degree of the core groups as a function of the selective pressure $\beta_S$. Panels on the left display curves for values of $\phi \leq \phi_c$. Panels on the right display curves for values of $\phi > \phi_c$. The black dashed line in the plots for $\kappa_c$ indicates the average degree of the network, which has been externally fixed to $\langle k \rangle = 5$.

Figure 4. Fraction of nodes and average degree of the periphery groups as a function of the selective pressure $\beta_S$. Panels on the left display curves for values of $\phi \leq \phi_c$. Panels on the right display curves for values of $\phi > \phi_c$. The black dashed line in the plots for $\kappa_c$ indicates the average degree of the network, which has been externally fixed to $\langle k \rangle = 5$.

Figure 5. (a) Value of the fraction of nodes $S$ which are part of the giant connected component as a function of the selective pressure $\beta_S$ and dilution probability $\phi$. (b) Variation in $S$ with respect to the case where no selective pressure is applied as a function of the selective pressure $\beta_S$ and dilution probability $\phi$.

Based on dynamical robustness against noise [25], but the onset of the bipartite structures were not seen in these other cases.)

In most cases, the results tend to change predictably with different values of the edge dilution probability $\phi$, however a qualitative change in behavior is seen when we cross the $\phi = \phi_c$ value, where $\phi_c = 1/\langle k \rangle$ is the critical percolation value for a fully random graph. For $\phi > \phi_c$ a fully random graph has a nonzero giant component even for $\beta_S = 0$, and thus the progression to core-periphery and bipartite structures proceeds as discussed above. However, for $\phi < \phi_c$ a fully random graph gets completely disconnected, and therefore the response of the structural changes to increasing $\beta_S$ is not continuous, but happens more abruptly, with the onset of core-group that is typically much denser. We observe also an interesting behavior for sufficiently large values of $\phi$, where the core group spans almost the entire network at its onset, with an average degree coinciding with the whole network. The mechanism driving the network structure as $\beta_S$ increases appears to be slightly different in this case, as it is the smaller set of “periphery” nodes that end up forming the smaller group of the eventual bipartite structure.

For $\phi = \phi_c$ we also observe a different behavior, where the onset of the core-periphery structure ceases to be
abrupt, and the change happens continuously. This seems to indicate that an infinitesimal optimization of networks that lie on the critical percolation threshold has an infinitesimal entropic cost (a similar behavior had been observed previously in the context of Boolean networks optimized against stochastic fluctuations [24]).

A more detailed overview of the combined effect of $\beta_S$ and $\phi$ can be seen in Fig. 4, which shows both the value of $S(\beta_S, \phi)$, but also the relative improvement $\Delta S(\beta_S, \phi) = S(\beta_S, \phi) - S(0, \phi)$ with respect to a fully random graph. Indeed most of the improvement happens around the critical value $\phi = \phi_c$.

Changing the value of the imposed averaged degree $\langle k \rangle$ only shifts the position of the transitions, which remain qualitatively the same. The value of the number of groups $B$ does not change at all the results obtained. Indeed, for any value $B > 2$, we find that it is possible to merge together two or more groups, without changing the ensemble properties, until only two groups remain. The structures identified above are then to be considered the only ones to emerge when the selective pressure against random removal of edges is the only driving mechanism.

### B. Modularity

Some networks tend to be clustered into groups of nodes that are more connected to themselves than to the rest of the network. This feature can be beneficial for the adaptability [6, 26] and stability [27] of biological systems, and also to the efficiency of technological systems where these modules are associated with tasks that can be executed in parallel.

The most typical way to quantify of this kind of assortativity pattern is via the modularity function [29]

$$Q(A, b) = \frac{1}{2E} \sum_{ij} \left( A_{ij} - \frac{k_i k_j}{2E} \right) \delta_{b_i, b_j},$$

where $E$ is the total number of edges in the network and $k_i = \sum_j A_{ij}$ is the degree of node $i$. The quantity above simply counts the frequency of edges observed between nodes of the same group, subtracted by the expected fraction in a fully random graph with the same degree sequence. The expected value for modularity for the SBM can be easily computed as

$$Q(m) = \sum_r m_{rr} - m_r^2.$$  

Note that for completely assortative SBMs with $m_{rr} = \delta_{rs}/B$, we have $Q(m) = 1 - 1/B$, so we achieve maximal modularity $Q(m) \to 1$ for an infinite number of perfectly isolated groups.

We can include the modularity as a fitness criterion into our framework by making $R(\omega, m) = Q(m)$ and coupling with its selective pressure $\beta_Q$, and proceeding to minimize the free energy

$$F(\omega, m) = -\beta_Q Q(m) - \Sigma(\omega, m).$$

In Fig. 6 we see the value of the modularity of the network ensemble as a function of the selective pressure $\beta_Q$. As the selective pressure increases, the network splits smoothly and progressively into fully symmetric groups of equal size with a larger number of connections inside each group. For low values of $\beta_Q$, the results obtained with different number of groups coincide, and then they start to diverge for higher values. This is because the actual number of groups populated starts off small and progressively increases for larger values of $\beta_Q$. Differently from the percolation scenario considered in the previous setting, we do not observe abrupt transitions of any kind.

### C. Multiple optimization criteria

We now turn to the situation where we seek to optimize both modularity and robustness against random edge removal. In principle, this would amount to a free energy given by

$$F(\omega, m) = -\beta_S S(\omega, m) - \beta_Q Q(m) - \Sigma(\omega, m).$$

However, this would mean that the same division of the network used to compute modularity would also be used to obtain the robustness. But here we want to be more general, and allow the modularity of the network to refer to a division that is not necessarily related to the one used to obtain the robustness. We do so by assuming that the partition used for the computation of robustness is a subdivision of the one used to obtain modularity, such that each of its $B_Q$ groups can be further divided into one, two or more groups, totalling $B_S \geq B_Q$ groups. This assumption is made without loss of generality, since any two independent partitions into $B_1$ and $B_2$ groups can always be equivalently decomposed into one with at most $B_1 \times B_2$ groups, which is itself a subdivision of a smaller one with $\min(B_1, B_2)$ groups. Based on this, we have the free energy given by

$$F(\omega, m, c) = -\beta_S S(\omega, m) - \beta_Q Q(m', m, c) - \Sigma(\omega, m).$$

![Figure 6. Modularity $Q$ as a function of the selective pressure $\beta_Q$ for different choices of the allowed number of groups $B$.](image)
where \( c = (c_1, \ldots, c_{B_S}) \) is a hierarchical grouping of the \( B_S \) groups, with \( c_r \in [1, B_Q] \) being the group membership of the group \( r \) used for the computation of the giant component \( S \). The modularity is therefore computed with the condensed matrix

\[
m'_{r<s}(m, c) = \sum_{rs} m_{rs} \delta_{r,c_r} \delta_{s,c_s}.
\]

We stress that for our calculations the identity of the group memberships are irrelevant, as we concern ourselves only with the resulting network structures. Therefore, we select \( B_Q = q \) and \( B_S = qk \), where each of the \( q \) groups used for the computation of \( Q \) are subdivided into exactly \( k \) groups. Again, this comes without a loss of generality, as we do not make any provisions about how large each group is, or even if they are occupied at all. Therefore this scheme is purely conventional, and does not impose any kind of inherent symmetry or network structure on its own. By choosing \( q \) and \( k \) sufficiently large, we can obtain any kind of modular structure used to compute either \( S \) or \( Q \), independently. For our calculations we have used mostly \( q = k = 2 \), which have proved sufficient to capture most of the structures seen, but we have investigated higher values as well, as we discuss later.

We minimized Eq. \( 21 \) for an ensemble of networks with \( \langle k \rangle = 5 \), and edge dilution probability \( \phi = 0.21 \). Fig. \( 7 \) shows the relative changes of the optimization criteria as a function of the selective pressures \( \beta_S \) and \( \beta_Q \), where \( \Delta S(\beta_S, \beta_Q) \) and \( \Delta Q(\beta_S, \beta_Q) \) are defined as

\[
\Delta S(\beta_S, \beta_Q) = S(\beta_S, \beta_Q) - S(\beta_S, 0) \tag{23}
\]

\[
\Delta Q(\beta_S, \beta_Q) = Q(\beta_S, \beta_Q) - Q(0, \beta_Q) \tag{24}
\]

and represent the relative variations in \( S \) and \( Q \) induced by the interplay between the selective pressures with respect to the case in which we optimized for each constraint in isolation. As the selective pressures is changed, we observe a variety of structural phases, representing diverse combinations of the modular, core-periphery and bipartite structures encountered previously. The transitions between the various structures can be either smooth or abrupt. In the latter case, we can distinguish three types of transitions. The first type of transition is linked to abrupt changes of the network structure and can be identified by sudden jumps in the group parameters. The second kind of transition occurs when the number of groups required to describe the system changes, but no significant jumps in the group parameters are observed. Finally, the third type of transition is a mixed transition, where a change in the number of groups required to describe the system is accompanied by an abrupt change of the group parameters. Furthermore, we also observe the presence of synergistic and antagonistic effects, whereby selecting for one fitness criteria can help (or hinder) optimizing for the other. We will discuss these effects in more detail depending on the region where they occur in the phase diagram, as follows.

1. Regions in the phase diagram

a. The low \( \beta_S \) and low \( \beta_Q \) regimes: For low values of \( \beta_S \), we can recover the behavior observed when selecting for modularity in isolation by varying \( \beta_Q \), and the network structure varies from a random graph, (a) (see Fig. \( 7 \)) to increasingly separated and modular structures, (c) and (d). Conversely, we note that the behavior observed when selecting for robustness against random failures in isolation is not recovered for low \( \beta_Q \). By increasing \( \beta_S \) at some fixed low \( \beta_Q \), the network initially follows the expected behavior and transitions from a random graph, (a), to a core-periphery structure, (e). However, for high \( \beta_S \) the network structure is now described by a four-group structure composed of two identical and interconnected core-periphery or bipartite structures, (f) and (g). This symmetric effect can be understood in terms of modularity. As \( \beta_S \) increases, the selective pressure against random edge removal pushes the network towards increasingly stronger bipartite structures. Since those structures have edges running predominantly between different groups, they would yield negative modularity values. Therefore, by splitting both “core” and “periphery” groups each into two random subgroups used for the computation of modularity, the network can escape the negative values with negligible entropic cost.
Note that, in principle, one could recover a modularity of zero and keep a two-group structure by simply keeping one of the two $B_Q$ groups empty. However, as we can see from Fig. 8, modularity is a monotonically increasing function of $\beta_Q$, meaning it will only be zero exactly at $\beta_Q = 0$. Maintaining a four-group structure where both $B_Q$ groups are populated allows the network to attain infinitesimally positive modularity values for $\beta_Q > 0$.

b. The high $\beta_S$ and high $\beta_Q$ regimes: If we increase $\beta_Q$ at some fixed high value of $\beta_S$, we once again observe that the optimization of modularity causes the symmetric structures observed above to become less interconnected until two separate and identical structures coexist, i.e. (g), (h), and (i). This symmetric pattern effect can be understood as direct consequence of both optimization criteria competing with each other: since forming a single mixed core-periphery/bipartite structure would yield low modularity, the overall structure is mirrored to preserve high fitness values according to both criteria.

More interesting effects occur if we consider the impact that increasing $\beta_S$ has at some fixed high value of $\beta_Q$. In this scenario, we once again observe symmetric structures, see (k) and (i). However, we also see the presence of regions where the network structure is described by an asymmetric three-group pattern, see (j) and (l). In these regions, we again observe the presence of either a core-periphery or bipartite structure as a result of the selective pressure towards robustness against random edge removal. The requirement to have a high fitness for modularity is instead reflected by the presence of an accompanying and distinct modular structure. This accompanying modular structure is always denser than a fully random graph and becomes increasingly dense as $\beta_S$ is increased, suggesting that the effects of the selective pressure against random edge removal are not limited to the core-periphery or bipartite structures.

c. Intermediate regimes: For intermediate values of $\beta_S$ and $\beta_Q$, the network transitions, both smoothly and abruptly, between the same structures described above. The only difference being the presence of an “island” where a three-group pattern again describes the network structure, see (m). In this region, the structure is that of a core-periphery pattern in which we now have two peripheries preferentially connecting to a dense set of core nodes. This structure remains substantially unchanged if we vary $\beta_S$. By increasing $\beta_Q$, however, one of the two peripheries becomes progressively smaller and less connected to the core, and the overall network structure closely resembles the one observed in (j).

2. Synergistic and antagonistic effects

To better understand the synergistic and antagonistic effects seen in Fig. 7, it is convenient to consider the relative variations over $Q$ and $S$ individually, as shown in Fig. 8. Based on this, we consider each effect in isolation as follows.

a. Modularity: Inspecting the diagram for $\Delta Q$ in Fig. 8, we can see that for low values of $\beta_Q$ and $\beta_S$ the network structure is essentially that of a fully random graph. By increasing $\beta_S$, we eventually encounter a synergistic region just above the $\beta^*$ transition line that exists when $\beta_Q = 0$ (see Fig. 8a). This indicates
that merely transitioning to a core-periphery structure is enough to guarantee some degree of improvement in modularity with respect to a random graph. This synergistic region extends until moderate values of $\beta_Q$, corresponding to the region in Fig. 6 in which modularity shows a rapid increase. For high values of $\beta_Q$ the synergistic effects vanish, as we now find ourselves in the region of Fig. 6 where the modularity reaches its plateau value, and no structural transition can provide an additional benefit with respect to the case in which we optimize for modularity in isolation.

What is perhaps more interesting is the small synergistic region in $\Delta Q$ around the $\beta$ transition line. In this region of the phase space, the network structure is described by a bipartite pattern and a separate modular division. It would appear that the emergence of a bipartite structure — driven by the selective pressure towards robustness against edge removal — forces more edges to be distributed within their own groups than would be the case had we selected for modularity alone, thus providing an increased fitness.

b. Robustness against random failures: In the $\Delta S$ phase space, we observe two principal regions in which synergistic (antagonistic) effects are present, labelled $A$ and $B$ in Fig. 8. In region $A$, the network structure is described by a core-periphery pattern accompanied by an isolated cluster which is always denser than a fully random graph. This structure is initially able to provide greater robustness against random failures than the corresponding two-group core-periphery structures we observed in Fig. 3. However, it also has a higher entropic cost, which is accounted by the selective pressure for modularity, and we observe a synergistic interplay between the two selective pressures. This three-group structure displays no significant changes as $\beta_S$ increases, and, eventually, the evolution of the core-periphery structures observed in Fig. 3 can provide greater robustness. At this point, the selective pressure for modularity reverses its role by pinning the less optimal three-group structure in place, and we observe an antagonistic interplay between the two selective pressures. Increasing $\beta_S$ even further, we eventually reach the point where it is more beneficial for the network to pay a further cost in entropy and split into two symmetric structures, in exchange for larger mutual fitness.

A similar picture occurs in region $B$, where the network structure is characterised by a bipartite pattern and an accompanying cluster which is always denser than a fully random graph. The onset of region $B$ happens for values of $\beta_S \leq \tilde{\beta}$, and the added bipartitness initially provides an increased fitness against random edge removal. However, the role of the selective pressure for modularity once again reverses as soon as $\beta_S > \tilde{\beta}$ and we cross the bipartite transition line observed when optimizing for robustness against random edge removal in isolation.

As mentioned at the beginning of the section, it would in principle be possible to obtain any kind of modular structure by choosing high enough values of $q$ and $k$. However, the computation of the free energy grows quadratically with $B_S$, making it computationally expensive to increase the number of groups used to model the network. Nevertheless, we have investigated regions of the phase diagram allowing us to probe in more detail how the allowed number of groups affects the results. Our findings appear to indicate that increasing the number of groups can exacerbate the synergistic and antagonistic effects, but does not alter the regions in which these are observed. However, increasing the number of groups can potentially give rise to different entanglements of the core-periphery, bipartite, and modular structures observed above.

As an example, we consider the two slices at fixed $\beta_S$ shown in Fig. 9. For each of these slices, we fix $q = 8$ and $k = 2$. Fig. 10 shows a comparison of the modularity as a function of $\beta_Q$ for both the $q = k = 2$ case studied above, and this new case with $q = 8$ and $k = 2$.

For slice $A$, we can see that the two curves coincide for low to moderate values of $\beta_Q$, with the network structure transitioning from a two-group core-periphery structure to a three-group core-periphery, where we now have two peripheries connecting to a dense core group (see (m) in Fig. 7). For higher values of $\beta_Q$ the curves diverge, as the higher value of $q$ in the $q = 8$, $k = 2$ case allows the network to populate more groups, thus increasing its

![Figure 9. Number of groups required to describe the system as a function of the selective pressures $\beta_S$ and $\beta_Q$, up to a maximum of $B = 4$. The solid black lines indicate the slices $A$ and $B$ discussed in the text.](image-url)
For slice $B$, we find ourselves in a region of the parameter space where the network topology is described by two symmetric core-periphery structures which get progressively disconnected as $\beta_Q$ is raised. Once again, the two curves coincide for low to moderate values of $\beta_Q$, but, as $\beta_Q$ increases, the access to a higher number of $B_Q$ groups in the $q = 8, k = 2$ case allows for more groups to be populated, and we observe different entanglements of core-periphery structures accompanied by isolated clusters, and, for high enough $\beta_Q$, we once again observe a mirroring effect in which the network topology is now described by eight symmetric core-periphery structures.

IV. CONCLUSION

We have introduced a framework to generate null models of optimized networks, which allow us to incorporate the effects that selective pressures toward some predefined set of criteria can have on the structural properties of the network. A central feature of our approach is the ability to incorporate an arbitrary number of criteria, allowing us to analyse more realistic scenarios in which network systems are subject to multiple interacting selective pressures.

We have applied this framework to analyse the emerging structures in systems subject to the joint optimization for modularity and robustness against random removal of edges, which we analysed both in isolation and in combination. In the case of modularity alone, we showed that by increasing the selective pressure, we observe network structures which progressively split into an increasing number of symmetric groups whose nodes predominantly connect amongst themselves. In the case of robustness against random failures, we instead identify two phase transitions in which the network structure transitions first to a core-periphery pattern, and then into an asymmetric bipartite one. The core-periphery structure is characterised by a smaller and denser set of “core” nodes which connect preferentially amongst themselves and a larger “periphery” whose nodes mostly connect to the core nodes. This structure allows for higher robustness as the random removal of any edge is unlikely to disconnect the core, and peripheral nodes remain connected via the core itself. By increasing the selective pressure further, the core group eventually becomes so dense that its nodes no longer require to preferentially connect amongst each other to ensure a high level of robustness. They instead connect predominantly to the periphery and we observe an asymmetric bipartite structure.

Finally, by combining both fitness criteria, we observed different combinations of the above structures, where the core-periphery and bipartite structures can either appear in duplicate (i.e. we observe two symmetric core-periphery or bipartite structures) or accompanied by an additional cluster which ensures high modularity values. Notably, we observed regions of the parameter space...
where the interplay between the selective pressures can have either synergistic or antagonistic effects, and optimizing for a specific characteristic can either facilitate or hinder optimizing for the other.

Our results show how the interaction between different selective pressures can be combined in simple network models, offering a platform to investigate the effects that different fitness criteria can have on the emerging network structures. Furthermore, our model parametrization is the same used to identify modular structure in empirical networks, and we expect these two approaches can be eventually combined in order to identify the dominant driving mechanisms of network formation from network data.
