ABSTRACT

Objective: Rapid Emergency Medicine Score (REMS) is an attenuated version of the Acute Physiology and Chronic Health Evaluation (APACHE) II score and has utility in predicting mortality in non-surgical patients, but has yet to be tested among the trauma population. The objective was to evaluate REMS as a risk stratification tool for predicting in-hospital mortality in traumatically injured patients and to compare REMS accuracy in predicting mortality to existing trauma scores, including the Revised Trauma Score (RTS), Injury Severity Score (ISS) and Shock Index (SI).

Design and setting: Retrospective chart review of the trauma registry from an urban academic American College of Surgeons (ACS) level 1 trauma centre.

Participants: 3680 patients with trauma aged 14 years and older admitted to the hospital over a 4-year period. Patients transferred from other hospitals were excluded from the study as were those who suffered from burn or drowning-related injuries. Patients with vital sign documentation insufficient to calculate an REMS score were also excluded.

Primary outcome measures: The predictive ability of REMS was evaluated using ORs for in-hospital mortality. The discriminate power of REMS, RTS, ISS and SI was compared using the area under the receiver operating characteristic curve.

Results: Higher REMS was associated with increased mortality (p<0.0001). An increase of 1 point in the 26-point REMS scale was associated with an OR of 1.51 for in-hospital death (95% CI 1.45 to 1.58). REMS (area under the curve (AUC) 0.91±0.02) was found to be similar to RTS (AUC 0.89±0.04) and superior to ISS (AUC 0.87±0.01) and SI (AUC 0.55±0.31) in predicting in-hospital mortality.

Conclusions: In the trauma population, REMS appears to be a simple, accurate predictor of in-hospital mortality. While REMS performed similarly to RTS in predicting mortality, it did outperform other traditionally used trauma scoring systems, specifically ISS and SI.

INTRODUCTION

Trauma and unintentional injury are the leading causes of death for all individuals less than 44 years of age which result in a major cost burden for the healthcare system. Current literature supports that early diagnosis and appropriate treatment both improve outcomes and are cost-effective. Over the past decade, scoring systems have been utilised to assess injury severity and provide an objective measure for treatment and appropriate allocation of healthcare resources. The Acute Physiology and Chronic Health Evaluation (APACHE II) is a validated scale that assesses severity of illness among non-surgical, surgical and intensive care hospital patients. The score incorporates body temperature, respiratory rate (RR), heart rate, mean arterial pressure (MAP), oxygenation of arterial blood, arterial pH, serum sodium and potassium levels, serum creatinine, haematocrit, white cell count and Glasgow Coma Scale (GCS).
With a reliance on laboratory tests such as blood chemistry analysis, APACHE II scoring remains impractical for rapid injury severity assessment required in the emergency department (ED) or in the field. The Rapid Emergency Medicine Score (REMS), an attenuated version of APACHE II, allows for prompt calculation. REMS is a composite score consisting of the GCS, RR, oxygen saturation, MAP, hazard ratio and age. Among non-surgical patients who present to the ED, REMS has proven to be a valid predictor of mortality.

While many ED scoring methodologies focus on evaluating short-term outcomes, REMS has been shown to predict mortality at 1 week (hazard ratio 1.34, 95% CI 1.30 to 1.37), 1 month (hazard ratio 1.30, 95% CI 1.27 to 1.32) and 3 months (hazard ratio 1.26, 95% CI 1.24 to 1.28). An additional study comparing area under the curve (AUC) for the Rapid Acute Physiology Score (0.64, 95% CI 0.59 to 0.69) and REMS (0.74, 95% CI 0.70 to 0.78) in non-surgical ED patients determined superiority of the REMS. Every point increase in the 26-point REMS score was associated with an OR of 1.40 (95% CI 1.36 to 1.45, p<0.0001) for in-hospital mortality. While there have been extensive publications reporting sound predicative validity for this score among non-surgical patients, the utility of REMS in the trauma population has yet to be analysed.

The purpose of this study was to evaluate REMS as a risk stratification tool to predict in-hospital mortality in traumatically injured patients. Secondary objectives included comparing REMS to the Revised Trauma Score (RTS), the Injury Severity Score (ISS) and the Shock Index (SI) to determine which scoring system was a superior predictor of mortality, in addition to examining the six components of REMS to determine which, if any, were most predictive of mortality.

**MATERIALS AND METHODS**

**Study design**

This was a retrospective chart review of the trauma registry at an urban academic American College of Surgeons (ACS) level 1 trauma centre. The study was reviewed by the hospital institutional review board, The University of Kansas Medical Center Human Subjects Committee and a waiver of informed consent was granted.

**Study population**

Analysis focused on 3680 patients with trauma aged 14 years and older admitted to the hospital over a 4-year period. Patients transferred from other hospitals were excluded from the study; for these patients, vital signs may have changed from initial values due to treatment at institution, affecting REMS calculations. Patients who suffered from burn or drowning-related injuries were also excluded from the study. Finally, 158 patients with vital sign documentation that was insufficient for REMS calculation were also excluded. Non-REMS injury score data (ie, SI, ISS, RTS) were missing from 47 patients; these patients were included in all the REMS analyses except for calculation of the AUC for their respective scoring systems.

**Protocol**

Variables collected included age, date and time of arrival, race, sex, systolic blood pressure (SBP), diastolic blood pressure, RR, heart rate, oxygen saturation, length of stay and GCS. The ISS and RTS scores were calculated by and obtained from the trauma registry. The MAP and SI (heart rate divided by SBP) were calculated during data analysis.

**Measurements**

REMS scoring requires RR, heart rate, MAP, GCS, age and oxygen saturation. In REMS calculation, age is assigned a value from 0 to 6, and the remaining five variables are each assigned a score from 0 to 4 (table 1). REMS is a sum of these values with a maximum composite score of 26, with higher values being indicative of worse prognosis.

In this study, REMS was compared to three currently utilised injury scoring systems, including SI, ISS and RTS, to determine which measure was superior in predicting mortality. SI is calculated by dividing heart rate by SBP and has proven useful in predicting mortality and the severity of illness in traumatically ill patients. Likewise, the ISS correlates with mortality. In contrast,
the ISS is an anatomically based scoring system based on injuries to major body regions including the head and neck, face, chest, abdomen and pelvic contents, extremities and pelvic girdle and external body surface.9 10 The ISS is useful for assessment following motor vehicle collisions. The ISS algorithm incorporates points from each region with a maximum score of 75 (higher values represent more serious trauma). Finally, the RTS can be used by prehospital emergency personnel to assist with the triage of injured patients. The variables include RR, SBP and GCS11 and the unweighted RTS is calculated by adding the values assigned for each parameter against a maximum possible score of 12.

Data analysis
Continuous variables are described using mean and SD. Similarly, categorical variables are described using frequency and percentage. Parametric tests were used for the comparisons between groups: χ² test in the case of categorical variables and the t test in the case of continuous variables. Correlations were tested using Spearman test. Sensitivity and specificity were plotted using the receiver operating characteristic curve. The discriminate power of REMS, RTS, ISS and SI was compared using the AUC. Statistically significant associations and differences were identified by p values of less than 0.05. All analyses were conducted using SAS V.9.3 (copyright 2002–2008 by SAS Institute Inc, Cary, North Carolina, USA).

RESULTS
Of the patients studied, 3489 (94.8%) lived and 191 (5.2%) died. Characteristics of the study sample are included in table 2. Patients who lived had a mean age of 36.5±17.0 years, 73.7% were men, 62.5% were Caucasian, the average REMS was 3.4 (±3.2) and the average length of stay was 7.6 (±15.4) days. Patients who died had a mean age of 43.7 years, 77% were men, 59.2% were Caucasian, the average REMS was 11.8 and the average length of stay was 4.4 days.

The study team looked at the distribution of patient mortality by each incremental REMS score (1–26). Based on this distribution, the authors used natural cut-offs as well as their clinical judgement to develop the REMS groupings used in the study. A higher REMS was associated with increased mortality (p<0.0001, table 3). Patients with REMS less than 6, from 6 to 9 and greater than 9 had mortalities of 0.9%, 6.7% and 39.3%, respectively. An increase of 1 point within the 26-point REMS was associated with an OR of 1.51 for in-hospital death (95% CI 1.45 to 1.58).

Patients with low REMS scores who died presented to the ED with lower median GCS than those who survived. The median GCS for patients with REMS of 3–5 and 6–9 who died was 1.5 (p<0.0001) and 8 (p<0.0001) points lower than those who lived. Patients with high REMS scores who lived presented to the ED with a higher median age than those who died. The median age for patients with REMS of 16–19 and 20–21 who lived was

REMS, Rapid Emergency Medicine Score.
45.5 (p=0.01) and 50 (p=0.13) years older than those
who died.
Secondarily, REMS was compared to three additional
injury severity scoring systems (table 4). REMS (AUC 0.91±0.02) was found to be similar to RTS (AUC 0.89 ±0.04) and superior to ISS (AUC 0.87±0.01) and SI
(AUC 0.55±0.31) in predicting in-hospital mortality
(figure 1). The mean SI for patients who lived was 0.69
(±0.22) and 0.79 (±0.40) for those who died. The mean
RTS for patients who lived was 7.4 (±1.3) and 3.5 (±2.7)
for those who died. Finally, the mean ISS score for
patients who lived was 11.3 (±10.0) and 30.0 (±14.6) for
those who died.
While multivariable logistic regression indicated that
heart rate and RR individually did not predict mortality,
the other four REMS parameters did (table 5). GCS was
the strongest predictor of mortality (OR 0.743, 95% CI
0.71 to 0.78). While not directly assessed by REMS,
injury type also impacts patient mortality rates (table 6).
Patients with penetrating trauma experienced higher
mortality rates than those with blunt force trauma (8.0%
vs 4.4%, p<0.0001).

DISCUSSION
Despite recent improvements in trauma systems and
their resulting decrease in preventable deaths, trauma
continues to be the leading cause of mortality for those
under the age of 44 years in the USA. Trauma systems
rely on imperfect and subjective tools to triage critically
injured patients to the appropriate centre. Currently,
emergency medical service (EMS) and trauma care pro-
viders utilise a variety of factors such as blood pressure,
RR, GCS, as well as mechanism of injury to prioritise
responses and resources. With increasing rates of ED
and trauma diversion, particularly in urban settings, effi-
cient allocation of resources is more crucial than ever.
Organised and inclusive trauma systems depend on
patients being routed to the closest and most appropri-
ate centre capable of caring for the patient. Any tool
that can match true severity with the highest possible
resource within the system may ensure that higher level
centres are able to concentrate on patients most in need
of their capabilities. In particular, REMS appears to
provide an effective balance between the predictive
ability and the practical application which are necessary
for the trauma setting. Unlike systems used elsewhere in
the hospital, REMS does not require invasive or time-
consuming lab values such as lactate, base deficit, mixed
venous oxygen saturation or cutaneous tissue oxygen
saturation. Rather, REMS utilises readily available para-
eters available both in the prehospital environment
and in the ED.
The current body of literature related to REMS exam-
ines its application among non-surgical medicine
patients. Studies conducted by Olsson et al have con-
cluded that use of the REMS among non-surgical
patients in the ED is powerful in predicting both

reasons may include that medicine patients are more likely to have chronic comorbidities that may contribute to differing baseline vitals leading to a score variation. In addition, medicine patients may have a greater portion of their score attributable to age in comparison to that of the trauma population, which often consists of younger, otherwise healthy adults. Similar to Goodcare et al, this study found that the REMS components correlated with mortality were GCS, oxygen saturation, age and MAP; of those, GCS was found to have the strongest predictor of mortality among the trauma population, while heart rate and RR did not exhibit any statistical significance.

Analysis suggests that GCS may be underweighted in the REMS calculation for patients with trauma. At the lower end of the REMS scale (scores of 3–5 and 6–9), patients who died presented with a lower average GCS than those who lived. For REMS of 3–5, the average GCS for those who died was 11.1 (9–12 is classified as a moderate head injury) compared to 14.2 (15–15 is classified as a mild head injury) for those who lived. For REMS of 6–9, the average GCS for those who died was 8.4 (≤8 is classified as a severe head injury) compared to 11.5 (moderate head injury) for those who lived. In a study of geriatric trauma, Champion et al found a difference in mortality between patients with trauma older than 65 (19%) and those younger than 65 (9.8%). This difference in mortality may be due to the factor of age and the weight it carries within the REMS calculation methodology. However, our findings suggest that age may be overweighted in the REMS calculation for patients with trauma. At the higher end of the REMS scale (scores of 16–19 and 20–21), patients who survived presented with a greater average age; in these cases, a greater portion of the composite REMS score came from age.

REMS was derived from the medicine population; as a result, the scoring system does not differentiate between injury types. For the trauma population, however, injury type is a significant factor in mortality prediction. A significant difference in average mortality rates was demonstrated in patients presenting with blunt (4.4%) versus penetrating (8%) injury types. Differences in mortality rates by injury type persist at all levels of REMS.

This study, which analysed a large number of patients with trauma within a single hospital system, does possess several limitations. First, this was a retrospective analysis. As with any such study, potential disadvantages include the possibility of selection bias. Second, the study excluded 158 potential records from the analysis due to missing patient data required to calculate REMS. Forty-seven patients were excluded from the calculation due to missing non-REMS injury scores (ie, RTS, ISS, SI). Finally, because the study is based on data from a single urban academic ACS level I trauma centre, attempts to extrapolate results to other trauma populations may not be reliable. Given the focused population, opportunities exist for future expansion and improvement, such as

| REMS | Blunt mortality (%) | Penetrating mortality (%) | p Value | Overall mortality (%) |
|------|---------------------|---------------------------|---------|-----------------------|
| 0–2  | 0.3                 | 0.5                       | 0.6375  | 0.3                   |

REMS, Rapid Emergency Medicine Score.
conducting a prospective study on the predictive capability of REMS on mortality, and using a larger, more diverse trauma dataset. Evaluating REMS in the prehospital setting and monitoring the change in REMS from initial EMS contact to trauma centre arrival may prove to be useful for EMS and for the ED by enhancing the effectiveness of the triage process, the appropriate routing of patients and the utilisation of trauma resources.

CONCLUSIONS

Though initially designed for the medicine population, REMS was found to be a strong predictor of in-hospital mortality for the trauma population. REMS performed similarly to RTS and outperformed several other traditionally used trauma scales including ISS and SI. This study also indicates potential opportunities to better apply REMS to the trauma population. REMS components heart rate and RR were found to have no statistically significant contribution in mortality prediction, while age and GCS were overweighted or underweighted in the REMS calculation, respectively. Injury type is an important predictor of mortality in patients with trauma, and it was not included in the REMS calculation. Each of these represents an opportunity for future study.
