Additional index words. Brassica oleracea, stable isotopes, metabolism

Abstract. Isotopic labeling of plants provides a unique opportunity for understanding metabolic processes. A significant challenge of isotopic labeling during plant growth is that isotopes must be administered without disrupting plant development and at sufficient levels for mass spectral analysis. We describe a system for isotopic labeling of leafy vegetables with $^{13}$C and demonstrate successful incorporation of $^{13}$C into anthocyanins of preheading red cabbage (Brassica oleracea L. var. capitata L.). 'Super Red' red cabbage seedlings were grown for 34 days in an airtight acrylic labeling chamber supplied with $^{13}$CO$_2$ to maintain 400 ppm of $^{13}$CO$_2$. Nutrient solution was delivered hydroponically at a constant rate of 228 mmol m$^{-2}$ s$^{-1}$. Upon canopy closure, anthocyanin development was promoted by reducing the nutrient solution concentration and reducing the temperature to 10.5°C ± 1.5°C. Total shoot fresh weight (FW) was 1556 g and root FW was 491 g at harvest. Analysis of red cabbage shoot tissue by high-performance liquid chromatography—tandem mass spectrometry indicated the presence of 37 anthocyanins, of which 14 are reported here for the first time. Mass shifts representing $^{13}$C incorporation into anthocyanins were evident in mass spectra of anthocyanins from labeled tissue and demonstrate successful isotopic labeling.

Isotopic labeling of plants is a powerful strategy for studying metabolic processes. Plant compounds that have incorporated isotopic labels are distinguishable from their unlabeled analogs by mass spectrometry, and therefore can be traced in complex biochemical matrices. In plant science, isotopic labeling has been used to study carbohydrate biosynthesis, nitrogen metabolism, and photosynthetic partitioning (Kollman et al., 1973; Schiltz et al., 2005; Yamagata et al., 1987). Isotopic labeling of plants consumed as foods has also provided unique opportunities for understanding human nutrient metabolism (Grusak, 1997; Novotny et al., 2003).

Isotopes can be introduced into plants through roots, stems, or leaves. Root uptake of nitrogen-15 ($^{15}$N)-enriched ammonium nitrate or urea has been used to characterize nitrogen distribution and remobilization in pea (Pisum sativum L.), orange (Citrus sinensis L.), and spring wheat (Triticum aesti-vum L.; Ma et al., 2006; Menino et al., 2007; Schiltz et al., 2005). Stem injection of isotopically labeled sulfur-35 ($^{35}$S) into hard red winter wheat was used to study grain protein content (Kahlon and Chow, 1989). Isotopes may be introduced through leaves by means of photosynthetic fixation of labeled CO$_2$. Using a pulse-chase technique in which Arabidopsis thaliana (L.) Heynh was exposed to $^{14}$CO$_2$ for 10 min, followed by exposure to natural CO$_2$ for another 10 min, Sun et al. (1999) measured carbon partitioning into starch and sucrose. Because of safety concerns with radioisotopes, $^{13}$C0$_2$ is often selected for metabolic studies. Partitioning and utilization of photosynthate in soybean [Glycine max (L.) Merr.] was evaluated by periodic exposure to $^{13}$CO$_2$ in a labeling chamber and harvests at different growth stages (Yamagata et al., 1987). Carbon losses in French beans (Phaseolus vulgaris L.) leaves during dark respiration were studied by isolating an illuminated attached leaflet in a $^{13}$CO$_2$-enriched chamber for 10 h, followed by isolation in a respiration chamber in darkness (Nogués et al., 2004). A similar technique was developed to measure carbon fluxes in leaflets of drought-stressed tomato (Solanum lycoper-sicum L.; Haupt-Herting et al., 2001). Whole-plant labeling with atmospheric $^{13}$CO$_2$ has been performed on larch (Larix Mill.) in a canopy-scale open air system over 5 d (Talhelm et al., 2007). Although this system was simpler than techniques using chambers or other enclosures, and $^{13}$C-enriched foliar respiration was detected, leaf incorporation of $^{13}$C was not significantly different from control trees.

Successful atmospheric labeling with $^{13}$CO$_2$ poses a number of challenges. Uniform labeling is highly advantageous because the resulting labeled molecules exist as a predominant isotopomer, thus improving mass spectral detection and structure identification. To ensure uniform labeling, plants must be housed in an airtight labeling chamber, and the seal cannot be broken for irrigation. An organic growth medium may not be used because microbial metabolism of carbon substrates will dilute the $^{13}$CO$_2$ with respired natural CO$_2$.

In this article, we describe a study to label organic compounds in leafy vegetables with $^{13}$C by cultivation in a controlled environment containing atmospheric $^{13}$CO$_2$ and to characterize labeled compounds by high-performance liquid chromatography—tandem mass spectrometry (HPLC-MS/MS). Due to our particular interest in anthocyanins, we have chosen red cabbage (Brassica oleracea var. capitata) as the crop for labeling, and we have used anthocyanin labeling as a primary measure of success.

Materials and Methods

'Super Red' red cabbage was grown in 10.2-cm-diameter pots in an airtight labeling chamber supplied with $^{13}$CO$_2$ starting from seedling stage (9 d after sowing; first true leaves

visible in >50% of seedlings) and ending at harvest after 34 d. The labeling chamber was placed on a stainless steel wire rolling cart (Metro, Wilkes Barre, PA) located in a walk-in M28 growth chamber (Environmental Growth Chambers, Chagrin Falls, OH).

**LABELING CHAMBER.** The labeling chamber consisted of two sections constructed of 6.4-mm-thick clear ultraviolet light-transparent acrylic sheet (Fig. 1). The upper section was a box (1.03 m long × 0.75 m wide × 0.84 m high) that was set on a base (1.10 m long × 0.82 m wide). The bottom edge of this box was immersed in a water-filled trough, thereby forming an airtight seal. \(^{13}\)CO\(_2\) concentration in the labeling chamber was measured by a WMA-4 IR gas analyzer (IRGA; PP Systems, Amesbury, MA) retrofitted with an erasable programmable read-only memory chip (V.1.44 SP1; PP Systems) that allowed the IRGA to be calibrated with \(^{13}\)CO\(_2\). A temperature and relative humidity probe (model CS500; Campbell Scientific, Logan, UT) in a radiation shield (model 41003; Campbell Scientific) was located in the labeling chamber 15 cm above the surface of the acrylic base. An axial fan (model 4C549A; Dayton Electric, Niles, IL) was positioned centrally on the upper surface of the labeling chamber to promote air mixing and uniform heat distribution. Six ports with 0.64-cm bulkhead fittings were located next to the axial fan to accommodate the following: 1) temperature/relative humidity probe signal leads, 2) axial fan power cord, 3) \(^{13}\)CO\(_2\) supply tube, 4) IRGA inlet sampling tube, 5) IRGA return flow tube, and 6) tube to barometer (model PTB101B; Vaisala, Woburn, MA).

Additional cooling capacity and relative humidity control were achieved by a heat exchanger consisting of four 0.55-m lengths of finned tubing (2.31 cm o.d.) connected in series and attached to an inside end wall of the labeling chamber. Water chilled by a refrigerated bath (model RTE-8; Neslab, Newington, NH) was supplied to the heat exchanger through braided vinyl tubing (1.6 cm o.d. × 1.0 cm i.d.) connected to a 1.0-cm hose barb adapter in a side wall of the labeling chamber. The air temperature inside the labeling chamber was controlled by the temperature of the water passing through the heat exchanger and by the air temperature outside of the labeling chamber. Condensate from the heat exchanger drained into the water trough. The water level in the trough was periodically reduced from the labeling chamber flowed at 0.4 L min\(^{-1}\) through Bev-a-

\[ \text{Line IV tubing (64 mm o.d. × 32 mm i.d.); Thermoplastic Processes, Stirling, NJ} \] to an in-line oxygen sensor (model 02S-F; Apogee Instruments, Logan, UT), then to the IRGA, which monitored \(^{13}\)CO\(_2\) concentration, and then returned to the labeling chamber. The IRGA was connected to a proportional-integral-derivative controller (model CN77322; Omega Engineering, Stamford, CT). When the \(^{13}\)CO\(_2\) concentration fell below 390 \(\mu\text{L} \cdot \text{L}^{-1}\), the proportional-integral-derivative controller activated a normally closed solenoid (model EW-98165-60; Asco Valve, Florham Park, NJ), thereby supplying \(^{13}\)CO\(_2\) to the labeling chamber. The \(^{13}\)CO\(_2\) (99.3 atom % \(^{13}\)C; Isotec, Miamisburg, OH) flowed from the source tank through Mazzerpur 95 tubing (64 mm o.d. × 32 mm i.d.; Mazzer Industries, Rochester, NY) to a mass flow meter (Cole-Parmer Instrument, Vernon Hills, IL), through the solenoid, and into the labeling chamber. Although the solenoid returned to its normally closed state when the IRGA measured 400 \(\mu\text{L} \cdot \text{L}^{-1}\) \(^{13}\)CO\(_2\), the \(^{13}\)CO\(_2\) concentration in the labeling chamber typically stabilized around 430 \(\mu\text{L} \cdot \text{L}^{-1}\) after 2 min of air mixing. A data logger (model CR23X; Campbell Scientific) recorded 5-min and 1-h mean, maximum and minimum values of \(^{13}\)CO\(_2\) concentration, \(O_2\) concentration, air temperature, relative humidity, barometric pressure, and the temperature of the heat exchanger in the labeling chamber. Data for the atmospheric pressure outside of the labeling chamber were obtained from the Beltsville Agricultural Research Center in Beltsville, MD.

**NUTRIENT DELIVERY SYSTEM.** Plants were subirrigated daily with a complete nutrient solution that contained 14.5 mmol L\(^{-1}\) of nitrogen at full strength (Robinson, 1984). A reservoir holding 60.5 L of solution was located under the labeling chamber. For 10 min each day, a fountain pump (model PU250/PP-399; Hydrofarm, Petaluma, CA) pumped solution through clear vinyl tubing (1.3 cm o.d. × 1.0 cm i.d.) through the base of the labeling chamber. Nutrient solution simultaneously returned to the reservoir by gravity flow through separate vinyl tubing of the same size. The peak depth of the solution in the base of the labeling chamber was 4.0 cm and from the time the pump was turned off, 25 min elapsed before all of the solution drained into the reservoir. Gas exchange between the labeling chamber and the outside air was prevented by the continuous presence of nutrient solution in the vinyl tubing.

**EXPERIMENTAL PROTOCOL.** To minimize \(CO_2\) evolution by microbial metabolism of carbon substrates, an inorganic growth medium was selected for red cabbage plants. The inside bottoms of 28 10.2-cm-diameter pots were fitted with sections of window screen to prevent loss of growth medium during drainage. Thirty grams of Turface MVP (Profile Products, Buffalo Grove, IL) was placed on the screen, followed by sufficient Greens Grade (Profile Products) to fill each pot to within 1.5 cm of the top. Turface MVP and Greens Grade are calcined clay products. Four 'Super Red' red cabbage seeds were planted in each pot, and all pots were placed in a growth chamber at 22 °C ± 1 °C. Constant light was supplied from fluorescent lamps and the photosynthetic photon flux (PPF) was 385 \(\mu\text{mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}\).

---

at the surface of the growth medium (10.2 cm above bench top).

After 9 d, a single seedling was selected for uniformity and vigor in each pot, and the remaining seedlings were cut at the level of the growth medium and shoots were removed. The pots were placed in the labeling chamber and distributed evenly, and the chamber was sealed. To reduce the concentration of natural unlabeled CO2, the labeling chamber was flushed with nitrogen until the IRGA read 154 μL.L⁻¹. The IRGA had been calibrated with 13CO2 and was about four times more sensitive to natural CO2 than 12CO2. Therefore, it was estimated that the actual natural CO2 concentration was 40 μL.L⁻¹. The solenoid was activated and 292 cm³ (standard temperature and pressure) of 13CO2 was injected into the labeling chamber, resulting in a CO2 (including 13C and 12C) reading of 519 μL.L⁻¹. After correcting for the increased IRGA response to natural CO2, the actual CO2 (13C and 12C) concentration was calculated to be 405 μL.L⁻¹ (IRGA final reading – IRGA initial reading + 40 μL.L⁻¹ of natural CO2).

Plants were grown in constant light supplied by eight 400-W metal halide lamps (model MS400/HOR; Sylvania, Danvers, MA) at a photosynthetic photon flux density (PPFD) of 385 μmol.m⁻².s⁻¹. The mean PPFD measured at five locations 10.2 cm above the base of the labeling chamber was 228 μmol.m⁻².s⁻¹.

Temperature and nutrient fertility were chosen to promote anthocyanin development during red cabbage growth. The temperature in the labeling chamber was maintained at 22.0 °C ± 0.5 °C for 26 d by setting the walk-in growth chamber temperature at 25.0 °C and varying the water bath temperature from 8.0 °C to 13.0 °C. The water bath temperature was increased over 26 d to offset the increasing transpirational cooling of the red cabbage. Low temperatures induce anthocyanin biosynthesis (Whipker et al., 1998). Therefore, for the next 8 d, the walk-in growth chamber temperature and water bath temperature were varied (16.0 °C to 14.0 °C and 2.5 °C to 0.0 °C, respectively) to maintain 10.5 °C ± 1.5 °C in the labeling chamber. Our objective with the nutrient solution was to provide suitable fertility for initial biomass accumulation (determined by canopy closure) and subsequently to supply limiting nitrogen, which upregulates genes involved in anthocyanin biosynthesis (Peng et al., 2007). Full-strength nutrient solution was supplied at the beginning of labeling and was replaced with full-strength solution 7 and 14 d later. On days 21 and 28, the nutrient solution was replaced with one-quarter-strength (3.6 mmol.L⁻¹ N) nutrient solution.

Plants were harvested in dim light 34 d after being placed in the labeling chamber. Shoots and roots were separated and fresh weights were recorded. All plant tissue was stored at −80 °C. Shoots to be measured for anthocyanin content were freeze-dried, ground in a coffee mill to a fine powder, and stored at −80 °C until analysis.

Evaluation of CO2 Increase at Start of Experiment. After the labeling experiment was completed, a study was conducted to determine the cause of the initial rise in CO2 measured during the first 4 d of labeling. Unlabeled CO2 concentrations were measured and compared in four situations. First, CO2 was measured for 7 d in the labeling chamber without the presence of pots, growth medium, or plants. Second, 28 pots containing the same growth medium as during the labeling experiment were incubated for 9 d at 22 °C ± 1 °C in constant light with a PPFD of 385 μmol.m⁻².s⁻¹. No seeds were planted. The pots were then moved into the labeling chamber and CO2 concentration was measured for 4 d, the point at which CO2 concentration returned to its initial value. Third, ‘Super Red’ red cabbage seeds were planted in growth medium in 28 pots and seedlings were produced as previously. Before moving the pots into the labeling chamber, all seedling shoots were cut and removed, leaving only roots in the growth medium. CO2 concentration was measured for 7 d. Fourth, red cabbage seedlings were grown in the same pots and growth medium. One seedling was selected in each pot, the shoots of all other seedlings were discarded and the roots were left in the growth medium. The pots with intact seedlings were moved into the labeling chamber and CO2 concentration was recorded for 7 d. In each case, the labeling chamber was held at 22.0 °C ± 0.5 °C, was subirrigated daily with full-strength nutrient solution, and the same light conditions as during the labeling experiment were used.

Confirmation of Labeling of Anthocyanins. To compare mass spectra of unlabeled anthocyanins with spectra of 13C-labeled anthocyanins, ‘Super Red’ red cabbage was produced in the labeling chamber with similar environmental conditions and using a supply of natural CO2 (98.9% 13CO2 and 1.1% 12CO2). Shoots were harvested, freeze-dried, and ground to a fine powder. Anthocyanins from labeled and unlabeled plant tissue were extracted and analyzed by HPLC-MS/MS as previously described (Charron et al., 2007). Briefly, 0.10 g of lyophilized tissue was extracted in 10.0 mL of 10% formic acid in methanol (v/v). A 0.75-mL aliquot was filtered through a 0.2-μm nylon filter, dried under nitrogen gas, and reconstituted in methanol: 10% aqueous formic acid (1:9, by volume). Extracted samples were analyzed on an Agilent Technologies (Palo Alto, CA) series 1100 HPLC with a model SL ion trap spectrophotometer. The column was an Agilent Zorbax StableBond C18 (150 x 4.6 mm i.d., 3.5 μm). Mobile phase A was 10% formic acid in water (v/v) and mobile phase B was methanol. The solvent gradient was 0 to 20 min, 5% to 15% B; 20 to 40 min, 15% to 22% B; 40 to 55 min, 22% to 30% B; 55 to 80 min, 30% to 35% B; 80 to 85 min, 35% to 100% B; 85 to 90 min, 100% B; 90 to 95 min, 100% to 5% B; 95 to 100 min, 5% B. Mass spectra of anthocyanins from unlabeled plant tissue were used for compound identification and were compared with mass spectra of anthocyanins from labeled plant tissue to characterize labeled anthocyanins. Authentic standards of cyanidin-3-glucoside (Indofine Chemical Co., Somerville, NJ) and cyanidin 3,5-diglucoside (ChromaDex, Irvine, CA) were used to aid in anthocyanin identifications.

Results and Discussion

System Performance. At harvest, the total shoot fresh weight (FW) of the 28 plants was 1556 g (mean ± sd = 56 ± 12 g) and the total root FW was 491 g (mean ± sd = 18 ± 5 g). The mass flow meter measured 156.8 L of 13CO2 injected into the labeling chamber during growth of the red cabbage. The temperature in the labeling chamber was successfully maintained at 22 °C ± 1 °C for 26 d and at 10.5 °C ± 1.5 °C for the final 8 d (Fig. 2A). The heat exchanger prevented condensation on the inside walls of the labeling chamber and was particularly important in removing heat produced by the lamps. This additional cooling capacity was an advantage over a previous system we developed that controlled the temperature of the labeling chamber only by regulating the exterior temperature (Kurilich et al., 2003). The relative humidity
increased from 65% to 85% as a result of the increased transpiration as plant biomass increased during the course of the experiment (Fig. 2B). There was a diurnal rise and fall in relative humidity that corresponded with daily subirrigation. Oxygen concentration increased from 20% to 29% (Fig. 2C). The rate of increase was highest at day 21 and decreased thereafter. Atmospheric pressure in the labeling chamber generally tracked the pressure outside of the chamber (data not shown). The continuous production of O$_2$ during the photosynthetic fixation of carbon would have produced a slightly higher pressure inside the labeling chamber relative to the outside, thereby creating a net flow out and minimizing contamination by outside air. This net outflow may have occurred at joints in the chamber or at plumbing connections.

To optimize the labeling of red cabbage anthocyanins with $^{13}$C, it was important to identify possible sources of unlabeled carbon. The CO$_2$ concentration in the labeling chamber increased significantly on day 26 and corresponded with a brief dark period resulting from a low temperature alarm in the walk-in growth chamber that turned off the lights. The CO$_2$ increase likely resulted from the carbohydrate oxidation pathways of dark respiration (Fig. 2D). The CO$_2$ produced would have originated from substrate that had previously incorporated $^{13}$C from the $^{13}$CO$_2$-enriched atmosphere. When light was restored, CO$_2$ levels were rapidly reduced by photosynthetic carbon fixation.

A more problematic event was the CO$_2$ increase measured during the first 43 h of the experiment. Within 1 h after the labeling chamber was sealed and the initial volume of $^{13}$CO$_2$ was injected, a rise in CO$_2$ was observed and the valve of the $^{13}$CO$_2$ source tank was temporarily closed. The rise in CO$_2$ concentration, which persisted until day 2, was therefore attributed to natural CO$_2$. Because the IRGA was calibrated for $^{13}$CO$_2$, the actual increase in natural CO$_2$ was about 25% of that measured by the IRGA. After correcting for the increased IRGA sensitivity to natural CO$_2$ and accounting for the volume of the labeling chamber (648.9 L), the volume of natural CO$_2$ present on day 2 was calculated to be 0.25% of the volume of $^{13}$CO$_2$ injected into the labeling chamber during the experiment. This fraction of natural CO$_2$ would have minimal impact on $^{13}$C incorporation into continuously synthesized compounds, but potentially could dilute $^{13}$C incorporation of compounds synthesized primarily at the beginning of labeling.

**INITIAL CO$_2$ INCREASE.** When the labeling chamber was sealed with no pots or growth medium, the CO$_2$ concentration decreased from 559 to 532 µL·L$^{-1}$ over 7 d (Fig. 3). The presence of pots with growth medium in the labeling chamber resulted in a CO$_2$ increase from 580 to 602 µL·L$^{-1}$ over 42 h, followed by a decrease to 512 µL·L$^{-1}$ on day 4. Although the growth medium is a clay-based material, it...
may contain sufficient carbon substrate to support microbial metabolism and respiration. Besides the respiratory CO\textsubscript{2} from possible microbial activity, the prolonged rise of CO\textsubscript{2} in the labeling chamber when pots with growth medium and roots were present indicated that roots left in the growth medium after thinning continued to respire detectable levels of CO\textsubscript{2}. Respiration of cut roots has been widely documented for fresh-cut root produce such as radishes (del Aguila et al., 2006). When intact seedlings were placed in the labeling chamber with growth medium and roots of cut seedlings, the CO\textsubscript{2} increase from microbial and root respiration was offset by carbon fixation. As shown in Fig. 3, after 3 d, CO\textsubscript{2} levels decreased to the set point required for solenoid activation, resulting in the sawtooth pattern reflecting CO\textsubscript{2} addition via the solenoid and CO\textsubscript{2} removal by photosynthesis.

**Anthocyanins in 'Super Red' Red Cabbage.** A growing body of evidence indicates that consuming anthocyanin-rich foods may provide several health benefits, including neuroprotection, amelioration of obesity, protection of cardiovascular health, and disruption of carcinogenic processes (Bell and Gochneau, 2006; Galli et al., 2006; Jayaprakasam et al., 2006; Shih et al., 2007). These health benefits have fueled interest in anthocyanin identification in various food sources. In this study, anthocyanin identification was based on mass spectra of unlabeled anthocyanins, which were compared with those of labeled anthocyanins with the same HPLC retention times. Structural characterization of previously reported anthocyanins has been described (Charron et al., 2007; McDougall et al., 2007; Wu and Prior, 2005a) and therefore we primarily discuss newly found anthocyanins. Nuclear magnetic resonance data have shown that hexoses of red cabbage anthocyanins consist primarily of diglucose and glucose attached to positions 3 and 5 of cyanidin, respectively, and that aliphatic and aromatic acids commonly are acylated to the glucose residues of position 3 (Idaka et al., 1987a, 1987b; Ikeda et al., 1987). Identifications of newly found anthocyanins were based on these nuclear magnetic resonance data, the determination that MS/MS fragmentation of anthocyanins occurs almost exclusively at the glycosidic bonds between the flavlyum ring and adjacent glycosides, and the finding that cleavage of ester linkages between glycosides and acylated groups has not been observed (Giusti et al., 1999). Acylated groups were determined by calculating combinations of aliphatic and aromatic acids commonly found in anthocyanins.

Thirty-seven anthocyanins were detected, including 14 that are reported here for the first time (Fig. 4 and Table 1). The same anthocyanins were present in labeled and unlabeled red cabbage, indicating that the labeling process did not significantly affect anthocyanin biosynthesis. To our knowledge, this is the first study of red cabbage anthocyanins for which the red cabbage cultivar was reported. Cultivar-dependent variation in anthocyanin profiles occur in other horticultural crops and may explain why we found previously unreported anthocyanins (da Silva et al., 2007; Pomar et al., 2005).

Peak numbers are used to represent the anthocyanins listed in Table 1. Cyanidin 3-diglucoside-5-glucoside (peak 5) is one of the predominant nonacylated anthocyanins in red cabbage and is the structure from which most of the acylated anthocyanins are derived (Wu and Prior, 2005a). We found exceptions to this pattern among the newly found anthocyanins. Peak 1 had the same fragmentation pattern as peak 5, having a dihexose at position 3 of cyanidin and a hexose at position 5. However, peak 1 eluted 6 min earlier than peak 5. Anthocyanins containing a galactose elute sooner than the same anthocyanins with a corresponding glucose (Wu and Prior, 2005b), indicating that peak 1 had one or more galactose residues. There were insufficient data to determine the identities of the hexoses associated with peak 1. Similarly, peaks 2, 7, and 8 had mass spectra indicating a single hexose at the 3- and 5-positions of cyanidin. Peak 7 was identified as cyanidin 3,5-diglucoside based on comparison of its retention time with that of an authentic standard, but the precise identifications of the hexoses of peaks 2 and 8 could not be determined.

Delphodinin differs from cyanidin by the addition of a hydroxyl group on the anthocyanidin B-ring. Peak 3 was tentatively identified as delphinidin 3-diglucoside-5-glucoside based on its mass spectrum ([M] m/z 789, MS/MS m/z 627 [M-glucose]-, 465 [M-diglucose]-, and 303 [delphinidin]-). Peak 4 was identified as delphinidin 3,5-diglucoside ([M] m/z 627, MS/MS m/z 465 [M-glucose]-, and 303 [delphinidin]-). Peaks 3 and 4 were minor anthocyanins but are noteworthy because delphinidin-based anthocyanins from red cabbage have not been previously reported.

The mass spectra of peak 12 revealed an MS/MS m/z ion of 449 [M-632]-. The loss of 632 units (u) corresponds to a residue at the cyanidin 3-position of diglucose acylated with caffeic and p-coumaric acids (324 + 162 + 146 u) or triglucose acylated with p-coumaric acid (486 + 146 u). The ambiguity of the identification of peak 12 arises because glucose and caffeic acid have the same molecular mass. Mass spectra of the 13C-labeled anthocyanins are discussed below and indicated that the loss of 632 u from peak 12 likely was triglucose+p-coumaric acid. Therefore, peak 12 was tentatively identified as cyanidin 3-(p-coumaroyl) triglucose-5-glucoside. The identifications of peaks 22, 23, and 32 were also initially obscured by the similar molecular masses of glucose and caffeic acid, but were...
facilitated by examination of the mass spectra of their $^{13}$C-labeled analogs. These compounds consisted of the cyanidin 3-diglcioside-5-glucoside backbone with two groups acylated to the diglucoside. Peaks 23 and 32 were isomers tentatively identified as cyanidin 3-(caffeoyl)(feruloyl) diglucoside-5-glucoside. Peak 22 was identified as cyanidin 3-(caffeoyl)(sinapoyl) diglucoside-5-glucoside. Peak 31, identified as cyanidin 3-(feruloyl)(sinapoyl) triglucoside-5-glucoside, had the same backbone as peaks 22, 23, and 32, but in contrast to these compounds, neither acyl group was caffeic acid.

Peaks 16, 27, and 34 were isomers with $[M]^{+}/m/z$ 1125, MS/MS $m/z$ 963 [M - glucose], and 449 [M - diglucose - 352]. The residue consisting of 352 u could be two ferulic acids (176 + 176 u) or one p-coumaric and one sinapic acid (146 + 206 u). The HPLC retention times of peaks 16, 27, and 34 were 43.4, 58.7, and 62.8 min, respectively, indicated a range of hydrophobicities but did not aid in conclusively identifying the two acylated groups for any of these peaks.

Peaks 20, 21, and 28 had $[M]^{+}/m/z$ 787 yielding MS/MS ions of $m/z$ 625 [M-glucose$^-$], 449 [M-338$^-$], and 287 [M-500$^-$]. The loss of 338 u could be explained by the loss of a hexose attached to ferulic acid (162 + 176 u) or the loss of a pentose attached to sinapic acid (132 + 206 u). The loss likely consisted of a pentose + sinapic acid, as supported by mass spectral analysis of the $^{13}$C-labeled anthocyanins. The exact identification of the pentose could not be determined, although xylose has been previously found in red cabbage anthocyanins (Charron et al., 2007; Wu and Prior, 2005a). The different retention times of peaks 20, 21, and 28 probably resulted from different sites of attachment of the sinapic acid and/or the identity of the pentose.

Wu and Prior (2005b) used a similar HPLC-MS/MS method to study fruit and berry anthocyanins and reported that cyanidin + hexose + pentose + sinapoyl was identified as cyanidin 3-(caffeoyl)(sinapoyl) diglucoside-5-glucoside.
3-arabinoside eluted shortly after cyanidin 3-glucoside and that cyanidin 3-xyloside eluted much after both compounds. However, it is not possible to apply these retention data to identify the pentose(s) in our study because the retention times likely were affected significantly by the sinapic acid residue.

Peak 36 ([M] m/z 655) had a single fragment, m/z 287 [cyanidin], corresponding to a loss of glucose + sinapic acid, and was identified as cyanidin 3-(sinapoyl) glucoside. Peak 37 was structurally similar to peak 36, differing only by the substitution of ferulic acid for sinapic acid, and was identified as cyanidin 3-(feruloyl) glucoside.

**Characterization of 13C-labeled anthocyanins.** Incorporation of 13C into anthocyanins of red cabbage grown in 13CO2 was confirmed by mass shifts in the [M] m/z and MS/MS m/z data in Table 1. For example, in unlabeled red cabbage, cyanidin 3-diglucoside-5-glucoside (peak 5) has 33 carbons and had [M] m/z 773 (Fig. 5A). In labeled red cabbage, cyanidin 3-diglucoside-5-glucoside has the same number of carbons but had [M] m/z 806 due to a shift of 33 u resulting from the 33 13C-labeled carbons (Fig. 5B). Although [M] m/z 806 was the ion of highest intensity for peak 5 in labeled red cabbage, other ions were present as well, representing molecules with incomplete incorporation of 13C. For example, [M] m/z 805 could result from the incorporation of 32 13C and 1 12C. Mass shifts caused by the assimilation of 13C were also evident in fragment ions. The MS/MS ions of unlabeled peak 5 were m/z 611 [M-glucose], 449 [M-diglucose], and 287 [M-glucose-diglucose] (Fig. 5C). In contrast, the analogous ions for peak 5 in labeled red cabbage were m/z 638 [M-glucose], 470 [M-diglucose], and 302 [M-glucose-diglucose] (Fig. 5D). These ions differ from those of unlabeled peak 5 because in labeled peak 5, 13C was incorporated into the six carbon positions of each glucose.

The mass spectra of unlabeled anthocyanins provided sufficient data to identify most of the anthocyanins. Furthermore, the predominant molecular ion in the mass spectra of the 13C-labeled analogs of identified anthocyanins corresponded with incorporation of 13C into all carbon positions. As a consequence of the predominance of completely labeled molecules, the mass spectra of 13C-labeled anthocyanins provided unique information that aided in identifying anthocyanins that could not be identified by their mass spectra when unlabeled. The sum of the number of carbons in each moiety
of an anthocyanin is equivalent to the nominal mass shift in the labeled anthocyanin. This result occurs because each $^{13}$C contributes an additional 1 u to the mass of a molecule compared with the mass of an unlabeled molecule. Peak 12 had $[M]^{m/z}$ 1081 when unlabeled and $[M]^{m/z}$ 1129 when labeled, a mass shift of 48 u. Therefore, peak 12 had a total of 48 carbons. The MS/MS $m/z$ ion 449 [M-632]$^-$ is consistent with the presence of cyanidin, which has 15 carbons, and a glucose at the 5-position, which has 6 carbons. Together, these moieties account for 21 of the 48 u of the $[M]^{m/z}$ mass shift observed in the labeled compound. The residue at the 3-position would be predicted to account for the remaining 27 u. The molecular mass of this residue (632 u) when unlabeled is consistent with diglucose acylated with caffeic and $p$-coumaric acids (324 + 162 + 146 u) or triglucose acylated with $p$-coumaric acid (486 + 146 u). However, triglucose (18 carbons) + $p$-coumaric acid (9 carbons) would contribute the expected remaining 27 u to the mass shift of 48 u, whereas diglucose (12 carbons) + caffeic acid (9 carbons) + $p$-coumaric acid (9 carbons) would contribute 30 u. Therefore, the mass spectra of $^{13}$C-labeled peak 12 supported the identification of peak 12 as cyanidin 3-$(p$-coumaryl)triglucoside-5-glucoside. Similar comparisons of carbon number and $[M]^{m/z}$ mass shift in $^{13}$C-labeled anthocyanins were used to help identify peaks 20 through 23, 28, and 32. However, consideration of carbon number and mass shift did not provide insight into the structures of the isomeric peaks 16, 27, and 34. These peaks had a residue that could consist of two ferulic acids or one $p$-coumaric and one sinapic acid. Both possible residues contain the same number of carbons (20) and therefore would contribute the same amount (20 u) to the $[M]^{m/z}$ mass shift when $^{13}$C-labeled. Thus, it is not possible to distinguish between the two residues based on the mass spectra of the labeled anthocyanins.

In conclusion, we labeled red cabbage grown in a controlled environment with atmospheric $^{13}$CO$_2$ and characterized 37 labeled and unlabeled anthocyanins by HPLC-MS/MS. Incorporation of $^{13}$C into anthocyanins provided insights useful for the elucidation of anthocyanin structure. This labeling system could be used for isotopic labeling of other crops that could be grown hydroponically. Although we labeled continuously from seedling stage to harvest, this system could also be used for pulse-labeling to produce photosynthate that could be traced through metabolic processes after brief exposures to $^{13}$CO$_2$. The fact that $^{13}$C is a stable isotope is a particular benefit because crops grown in this labeling system would be suitable for human nutrition studies that evaluate bioavailability of potentially healthful plant compounds.
