ABSTRACT

We present our analysis of the Gemini/NICI H-band data of HD 95086, following the discovery of the planet HD 95086 b in L′. The H-band data reach a contrast of 12.7 mag relative to the host star at 5σ levels in the location of HD 95086 b, and no point source is found. Our non-detection and H − L′ color limit rules out the possibility that the object is a foreground L/T dwarf and that, if it is bound to HD 95086, it is a genuine planetary mass object. We estimate a new pre-main-sequence isochronal age for HD 95086 of 17 ± 4 Myr, which is commensurate with previous mean age estimates for the Lower Cen-Crux subgroup. Adopting an age of 17 Myr, the color limit is inconsistent with the COND model, marginally consistent with the BT-SETTL model, and consistent with the DUSTY model.

Key words: planets and satellites: detection – stars: individual (HD 95086)

Online-only material: color figure

1. INTRODUCTION

Rameau et al. (2013) reported the probable detection of a 4 to 5 Jupiter mass companion to HD 95086 lying at a projected separation of 56 AU. The host is a young (17 ± 4 Myr; see Section 4.1) A8 type star. The large infrared excess (Chen et al. 2012) suggests that the star is harboring a debris disk, as yet unresolved.

The discovery at the L′ band (3.8 μm), using the angular differential imaging technique (ADI; Marois et al. 2006), was a 9σ detection in the first epoch. The second epoch suffered from poor observing conditions, resulting in a 3σ re-detection of the planet. The astrometric precision allowed for the rejection of a background object with nearly 3σ probability. Rameau et al. (2013) also carried out Ks (2.18 μm) observations that also suffered from bad observing conditions. This resulted in low Ks sensitivity and a non-detection. These observations were used to conclude that the detection at L′ was likely inconsistent with a background star. Such a non-detection rejected the background hypothesis and suggested a red object with Ks − L′ > 1.2 mag.

With a predicted temperature of Teff ≃ 1000 K (compared to the 1600–1700 K of β Pic b, and 800–1100 K for HR8799 bcde; Bonnefoy et al. 2013; Currie et al. 2011; Skemer et al. 2012), a giant planet will have an atmosphere close to the L-T spectral transition, where the effect of reduced surface gravity (characteristic of young and low-mass companions) is expected to dramatically affect the balance between dust formation and settling in the atmosphere (Stephens et al. 2009). If the companion is real, it would be a benchmark for spectroscopic studies of low-mass giant planets since it would be one of the lightest directly imaged planets, and key to testing predictions about dust settling in low-gravity atmospheres. The methane bands seen in mature brown-dwarfs at a similar temperature as HD 95086 b might also be reduced (or lacking) due to the effect of reduced surface gravity, which in turn triggers non-equilibrium chemistry of CO/CH4 (Hubeny & Burrows 2007).

Low-resolution spectroscopy is highly challenging with the present instrumentation given the contrast and faintness of HD 95086 b (Vigan et al. 2012). Broad band photometry is currently the only way to derive of the color of the companion and constrain its atmospheric properties. We examine our H-band NICI data9 taken in 2012, the same epoch as the L′ discovery image. We do not detect the companion in our H-band data, allowing us to derive a lower limit to the H − L′ color and reject a foreground contamination hypothesis.

In Sections 2 and 3, we describe our observations and our derived upper H-band limit. In Section 4, we discuss the age as determined by isochrone fitting and we show that the very red color rejects the foreground contamination hypothesis.

2. OBSERVATIONS

2.1. Data

Observations of HD 95086 were taken on UT 2012 March 19, 26, and 30 using the NICI camera (Toomey & Ftaclas 2003) on Gemini South in the H-filter (λ = 1.65 μm and Δλ = 0.29 μm) as part of a survey looking for gas giant planets around young stars with IR excesses (PI: V. Bailey). The camera was configured with the broad H band filter and the 0′.32 coronagraphic mask. The integration times for individual science frames are 55.0 s (5 coadded readouts of 11.0 s each). The details of the observing log for these data is listed in Table 1. Five percent of the frames are rejected per night due to poor alignment of the central star under the mask. The instrument was configured in telescope mode (PI: V. Bailey).

9 Taken as part of a survey of young stars with debris disks (PI: V. Bailey).
pupil tracking mode to keep the point spread function (PSF) structure from the telescope optics fixed with respect to the orientation of the detector. As a consequence, the position angle (P.A.) of the sky on the detector underwent rotation of 19°, 25°, and 25° on each of the nights, respectively.

2.2. NICI Data Reduction

Calibration data consists of dark frames with the same integration time and flats from the nights of March 19 and 26. The flat field images were dark-subtracted, and all individual flat field images were normalized by their median and combined together with a clipped mean to form a final normalized flat field image.

The dark frames were subtracted from the science frames and then the dark-subtracted science frames were divided by the normalized flat field frame. A bad pixel mask was constructed from pixels in the flat field frame that were greater than 1.2 or less than 0.8 in value. These bad pixels were interpolated over using adjacent good values in the science frames. Hot, cold, and flaky pixels were found and interpolated over in individual science frames by their values being more than 1000 counts different from the median of a 3 × 3 box centered on that pixel. Finally, the NICI distortion correction was applied to the images in order to perform astrometry on the additional background sources in the field of view.

2.3. Photometric Calibration

Due to the radial transmission function of the apodizer (Wahhaj et al. 2011) and the level of adaptive optics correction on the central star, photometric calibration was performed using a background star visible 4.5′ away from the primary star in the images. It was first detected by Kouwenhoven et al. (2005) and confirmed as a background object by Rameau et al. (2013). This background star was used as a photometric reference to determine the flux calibration and sensitivity in our H-band data. The NICI coronagraphic transmission curve is not yet published, thus to determine the near-infrared photometry of the background star, we utilize archival photometry from Hubble Space Telescope (HST) NICMOS data taken in 2007 (program 11157, PI: Joseph Rhee). The calibrated mosaic files provided by the HST archive are background-subtracted and normalized by exposure time. Two images, one per roll angle, are taken in each F110W and F160W; each of the four images has a total exposure time of 895 s. We roll-subtracted each pair of images, and used the aperture diameter and corresponding aperture correction recommended by the NICMOS data reduction handbook for NIC2. We derived the magnitudes in F110W and F160W of 13.63 ± 0.05 and 12.81 ± 0.05 for the background star. We used the transformations of Stephens et al. (2000) to derive J and H magnitudes of 13.25 ± 0.10 and 12.81 ± 0.10, respectively.
from 0.6 to between 10 and 14 mag fainter than the primary star, the star was used to generate the artificial planets by rescaling the combined to determine the 5σ model planet (12.5 mag) (for details see Section 4.2). The contrast curve is shown in Figure 2.

We injected artificial sources in all three nights of data to determine the 5σ detection limit. The background flux to between 10 and 14 mag fainter than the primary star, from 0.55 to 0.8 in 0.05 increments. The signal-to-noise (S/N) of the resulting fake planet is determined by the following equation:

\[
\text{(S/N)}_{\text{planet}} = \frac{F_{\text{planet}}}{\sigma(r) \sqrt{\pi r^2_{ap}}} 
\]

where \(F_{\text{planet}}\) is the sum of the flux in an aperture with a radius, \(r_{ap}\), of 2 pixels, \(\sigma\) is the root mean square of the pixels in a 340′′ arc at the same radius around the star (excluding the planet itself), and \(r\) is the width of the arc (2 pixels). We can then construct the distribution of S/N at various source magnitudes, and determine the 5σ detection limit by interpolation at a given radius from the star. The 5σ contrast curve is shown in Figure 2.

To make sure the source brightness is not affected by the NICI coronagraph, we extrapolated the transmission measured in the CH₄ filter (Boccaletti et al. 2013), assuming a linear relation with wavelength, and concluded that it should have nearly 100% transmission at greater than 0.6. Since the planet is detected at a separation of 0.624, this is within the 100% transmission regime.

4. ANALYSIS

4.1. Stellar Parameters and Age

HD 95086 was kinematically selected as a member of Lower Cen-Crux (LCC) based on its Hipparcos astrometry by de Zeeuw et al. (1999), and it has been included in several later studies as a member (e.g., Rizzuto et al. 2012; Chen et al. 2012). The mean age of the LCC subgroup defined by the >1 \(M_\odot\) stars is \(~16–17\) Myr, however, the inferred age spread of the group (\(~10\) Myr) hints that adoption of the mean subgroup age for a given star may be problematic (Mamajek et al. 2002; Preibisch & Mamajek 2008; Pecaut et al. 2012). The revised Hipparcos astrometry for the star from van Leeuwen (2007) differs negligibly from the original value, and indeed Rizzuto et al. (2012) again included HD 95086 in a recent analysis, so we regard the kinematic membership as secure.

The Hipparcos catalog quotes photometry of \(V = 7.36\) and \(B - V = 0.230 \pm 0.004\). If the intrinsic colors of HD 95086 are similar to that of A8V dwarf stars, then their mean color is \(B - V = 0.25\) (Pecaut & Mamajek 2013), with an rms spread of \(\pm 0.04\) mag. This is not surprising, as low reddening values \((E(B - V) < 0.05\) mag) are ubiquitous for stars within 90 pc in the general direction of HD 95086 (Reis et al. 2011). Based on this discussion, we adopt \(A_V = 0.02 \pm 0.02\) mag as a reasonable estimate that brackets the range of plausible extinctions and confirm the spectral type discussion in Rameau et al. (2013).

We calculate an absolute magnitude of \(M_V \approx 2.6\), which places the star near the main sequence (MS). The combined constraints of spectral type A8 \(\pm 1\) (assumed uncertainty) and restricting the plausible reddening value to be \(E(B - V) < 0.05\) leads to an effective temperature estimate of \(7550 \pm 100\) K (\(\log(T_{\text{eff}}) = 3.878 \pm 0.006\)) and \(V\)-band bolometric correction of \(B_C = 0.040 \pm 0.002\) (statistical) \(\pm 0.026\) (systematic), where the systematic uncertainty reflects differences in the bolometric magnitude scales among six studies (Code et al. 1976; Balona 1994; Flower 1996; Bessell et al. 1998; Bertone et al. 2004; Masana et al. 2006). Combining the Hipparcos \(V\) magnitude (assuming \(\pm 0.01\) mag uncertainty), the revised Hipparcos parallax, and our stated extinction and bolometric magnitude values, we estimate the following parameters for HD 95086: apparent bolometric flux \(f_{\text{bol}} = 28.52 \pm 0.9\) pW m\(^{-2}\), absolute V magnitude \(M_V = 7.38 \pm 0.03\), absolute bolometric magnitude \(M_V = 2.60 \pm 0.09\), and \(\log(L/L_\odot) = 0.863 \pm 0.035\) dex.

In Figure 3, we plot the H-R diagram point for HD 95086 with Dartmouth isochrones from Dotter et al. (2008) adopting approximately protosolar composition of \(Y = 0.26\) and \(Z = 0.017\). The star is slightly above the zero-age main sequence.
(ZAMS), and appears consistent with pre-MS age 16 ± 2 Myr. Using three other sets of pre-MS evolutionary tracks, we find the following ages: 15 Myr (D’Antona et al. 1997), 17 Myr (Yi et al. 2003), and 24 Myr (Siess et al. 1997). Note that models are in general agreement on the mass of HD 95086: ~1.7 \( M_\odot \).

Taking into account the different models and observational uncertainties, we estimate a final individual pre-MS isochronal age estimate of HD 95086 of 17 Myr (±2 Myr statistical, ±4 Myr systematic, total uncertainty ~±4 Myr). This is commensurate with the mean LCC subgroup age (Mamajek et al. 2002; Pecaut et al. 2012).

Two factors which could conspire to ruin our age estimate are (1) unresolved binarity (which would move the star older, closer to the ZAMS), and (2) if the star is an interloper whose H-R diagram position and kinematics could conspire to masquerade the star appear as a likely LCC member. In the unlikely scenario that the star is an interloper, its H-R diagram position would be consistent with an MS isochronal age of ~270 Myr.

4.2. Color Constraints

At the angular separation of the planet (0′624), we are sensitive to an H-band contrast of 12.7 mag relative to the host star for a 5\( \sigma \) point source detection. This is an apparent magnitude of 19.57 mag. Using the Rameau et al. (2013) apparent 

\[ L' \] 

magnitude of 16.49, we derive an \( H - L' \) lower limit of 3.1 ± 0.5 mag for the planet at 5\( \sigma \).

The expected H-band contrast of the planet, given the measured \( L' \) magnitude (Rameau et al. 2013), is 12.03 ± 1.0 mag based on the COND model (Baraffe et al. 2003) and 12.50 ± 1.0 mag based on the BT-SETTL model (Allard et al. 2013; Figure 2). The error is propagated from the uncertainty in the \( L' \) magnitude in Rameau et al. (2013). The contrast curve demonstrates that our data are sensitive enough to detect a planet for the COND models (\( S/N > ~4 \)) and the BT-SETTL models (\( S/N > ~2.5 \)). Instead, we detect no point sources at such brightness in our H-band data.

The expected H magnitudes for an unreddened A/F star, M dwarf, and T dwarf interlopers which are at the same distance as HD 95086 are 16.5, 17.5, and 18.5 (see triangle, Figure 2), respectively. This is far brighter than our 19.57 detection limit at the angular separation of the companion. If the companion were a T dwarf at the distance of HD 95086 or closer, we would have seen it based on our color and sensitivity limits. An unreddened K giant would have to be at 40 kpc in order to have the same color and sensitivity limits as HD 95086 b. We detect no point sources in our data, verified through three independent pipelines. Our deep dataset provides an \( H - L' \) lower limit, which rules out foreground L/T dwarfs and distant background K giant contaminants. If the object is bound to HD 95086, our color limit is inconsistent with the COND model, marginally consistent with the BT-SETTL model, and consistent with the DUSTY model at our derived age of 17 ± 4 Myr. Future astrometric observations are necessary.
to establish the nature of this object. This extremely red object demonstrates the importance of $L'$ band for planet detection as planets may be much redder than models predict.
