ABSTRACT

Context. The space telescope CoRoT searches for transiting extrasolar planets by continuously monitoring the optical flux of thousands of stars in several fields of view.

Aims. We report the discovery of CoRoT-10b, a giant planet on a highly eccentric orbit (\( e = 0.53 \pm 0.04 \)) revolving in 13.24 days around a faint (V=15.22) metal-rich K1V star.

Methods. We use CoRoT photometry, radial velocity observations taken with the HARPS spectrograph, and UVES spectra of the parent star to derive the orbital, stellar and planetary parameters.

Results. We derive a radius of the planet of 0.97 ± 0.07 R\(_{\text{Jup}}\) and a mass of 2.75 ± 0.16 M\(_{\text{Jup}}\). The bulk density, \( \rho_p = 3.70 \pm 0.83 \) g cm\(^{-3}\), is ~ 2.8 times that of Jupiter. The core of CoRoT-10b could contain up to 240 M\(_{\text{Earth}}\) of heavy elements.

Moving along its eccentric orbit, the planet experiences a 10.6-fold variation in insolation. Owing to the long circularisation time, \( \tau_{\text{circ}} > 7 \) Gyr, a resonant perturber is not required to excite and maintain the high eccentricity of CoRoT-10b.

Key words. planetary systems – stars: fundamental parameters – techniques: photometric – techniques: spectroscopic – techniques: radial velocities.

1. Introduction

CoRoT is the pioneer space mission dedicated to the detection of extrasolar planets via the transit method (Baglin 2003; see Auvergne et al. 2009 for a detailed description of the instrument and its performance). To date it has led to the discovery of ten extrasolar planets: CoRoT-7b, the first super-Earth with measured radius and mass (Léger et al. 2009; Queloz et al. 2003; three inflated hot Jupiters, CoRoT-1b (Barge et al. 2008), CoRoT-2b (Alonso et al. 2008a) and CoRoT-5b (Rauer et al. 2005); CoRoT-3b, “the first secure inhabitant of the brown dwarf desert” (Deleuil et al. 2008); two Jupiter-like planets with an orbital period of approximately 9 days, CoRoT-4b (Aigrain et al. 2008b) and CoRoT-6b (Fridlund et al. 2010); the long-period temperate giant planet CoRoT-9b (Deeg et al. 2010), and the hot Super-Neptune CoRoT-8b (Borde et al. 2010).

Here we report the discovery of the giant planet CoRoT-10b that orbits its parent star in 13.24 days, moving along a highly eccentric orbit with \( e = 0.53 \pm 0.04 \). It is therefore one of the few known transiting planets with \( e \gtrsim 0.5 \), such as HD 147056b (alias HAT-P-2b, \( e = 0.52 \) and orbital period \( P = 5.63 \) days; Bakos et al. 2007; Pál et al. 2010), HD 17156b (\( e = 0.67 \) and \( P = 21.22 \) days; Barbieri et al. 2007, 2009) and HD 80606b (\( e = 0.93 \) and \( P = 111.44 \) days; Moutou et al. 2009; Winn et al. 2009; Hébrard et al. 2010). Eccentric transiting planets include also those with a smaller eccentricity, notably the recently discovered WASP-8b (\( e = 0.31 \) and \( P = 8.16 \) days; Queloz et al. 2010) and HAT-P-15b (\( e = 0.19 \) and \( P = 10.9 \) days; Kovács et al. 2010), the massive planet XO-3b (\( e = 0.26 \) and \( P = 16 \) days; Johns-Krull et al. 2008; Winn et al. 2008) and the two Neptunes GJ 436b (\( e = 0.15 \) and \( P = 2.64 \) days; Gillon et al. 2007a,b; Alonso et al. 2008) and HAT-P-11b (\( e = 0.20 \) and \( P = 4.89 \) days; Bakos et al. 2010).

Transiting planets in eccentric orbits are very intriguing and interesting objects as they allow us to study ongoing tidal dissipation and its impact on the planet radius (Ibgui et al. 2010), atmospheric circulation in the case of a strong variation in insolation (Langton & Laughlin 2007), and the dynamical orbital evolution including the gravitational interaction between planets in a multiple system (planet-planet scattering; e.g. Marzari & Weidenschilling 2002 or the secular influence of a possible distant stellar companion (Kozai mechanism; Kozai 1962).

2. CoRoT observations

The parent star of CoRoT-10b, i.e. the CoRoT target LRc01_E2_1802, is a V = 15.22 star and has been observed in the stellar field pointing towards the constellation of Aquila during the first CoRoT long run LRc01 (Cabrera et al. 2009). Its magnitudes in several photometric bands and its coordinates are reported in Table 1. CoRoT observations of this target lasted for 142.07 days, from the 16th of May up to the 15th of October 2007, and provided us with monochromatic (white channel) data (Auvergne et al. 2009).

Transits by CoRoT-10b were first discovered in “alarm mode” (Surace et al. 2008), i.e. while CoRoT observations were still ongoing, which permitted us to change the temporal sampling from 512 s to 32 s after HJD 2454305.11. In total, 210248 photometric measurements were obtained, 198752 in the 32 s oversampling mode. Fig. 1 shows the CoRoT-10 light curve with the nominal sampling of 512 s, filtered from a) outliers that are produced by proton impacts during the crossing of the South Atlantic Anomaly of the Earth’s magnetic field by the satellite; and b) several jumps, with a typical duration shorter than 1 day, due to hot pixels. Corrections for the CCD zero offset, sky background, Earth’s scattered light and jitter variations were carried out by the latest version 2.1 of the CoRoT reduction pipeline. Unlike CoRoT-2 (Lanza et al. 2009), CoRoT-6 (Fridlund et al. 2010) and CoRoT-7 (Lanza et al. 2010), the light curve of CoRoT-10 is relatively quiescent and does not show flux variations due to the presence of starspots and photospheric faculae greater than a few mmag. It shows a long term decrease of ~ 2.5% attributable to CCD ageing (Fig 1). The rms of the nominal and oversampled photometric points is 0.0013 and 0.0046 in relative flux units, respectively.

A total of 10 transits with a depth of ~ 1.3% are visible in the light curve (Fig. 1). A zoom of one of the five 32 s oversampled transits is shown in Fig. 2. The transit ephemeris, reported in Table 4, was derived from a linear fit to the measured transit mid points determined by a trapezoidal fitting of each transit. It gives an orbital period of 13.2406 ± 0.0002 days.

3. Ground-based follow-up observations

3.1. Radial velocity observations

We performed radial velocity (RV) observations of the star CoRoT-10 with the HARPS spectrograph (Pepe et al. 2002b, Mayor et al. 2003) at the 3.6-m ESO telescope (La Silla, Chile). HARPS was used with the observing mode obj_AB, without acquisition of a simultaneous Thorium lamp spectrum in order to monitor the Moon background light on the second fibre. The intrinsic stability of this spectrograph does not require the use of lamp calibration spectra, the instrumental drift during one night being in our case always smaller than the stellar RV photon noise uncertainties. HARPS data were reduced with the on-line standard pipeline and radial velocities were obtained by a weighted cross-correlation with a numerical spectral mask for a K5V star (Baranne 1996; Pepe et al. 2002a).
The first two measurements of CoRoT-10 were made on June 2008. Seventeen additional measurements were obtained from June to September 2009. Seven of our nineteen measurements were strongly contaminated by the moonlight: the radial velocity of the Moon was close to that of CoRoT-10 and affected both the RV measurements and the bisector lines. We developed a software correction using the Moon spectrum simultaneously acquired on fibre B: it consists in subtracting the cross-correlation function (CCF) of fibre B, containing the Sun spectrum (reflected by the Moon), from the CCF of the fibre A, containing the stellar spectrum. The correction was applied when the two CCF peaks were close in radial velocity. For CoRoT-10, corrections in the range between 50 and 550 m s$^{-1}$ were applied for seven measurements. To be conservative, we added quadratically 30 m s$^{-1}$ of systematic errors to these seven corrected measurements.

Photometric observations during and outside the transit were carried out at the 1.20 m telescope of the Observatoire de Haute Provence during the nights of the 18th of June and the 15th of July 2009, respectively. Such observations are complementary to the radial velocity measurements and are required to definitively exclude the possibility that the transits detected in the CoRoT light curve could be produced by a background eclipsing binary which contaminates the CoRoT aperture mask of the star (Deeg et al. 2009). The latter covers $\sim 16'' \times 14''$ on the sky and contains two main background contaminants: one is 3.78 mag fainter in V and is located at $\sim 6.5''$ from CoRoT-10 toward South-West; the other one is 4.22 mag fainter in V and is $\sim 7.5''$ toward North-East (see Fig. 6). Differential photometry shows an “on-target” transit with the same depth as observed in the CoRoT light curve. None of the two contaminants exhibits significant flux variations that can mimic the transits observed in the CoRoT-10 light curve.

### 4. Transit fitting

In order to perform the transit fitting, first of all we filtered the raw light curve from outliers due to impacts of cosmic rays.
Table 2. Radial velocity measurements of CoRoT-10 obtained by HARPS. HJD is the Heliocentric Julian Date. The seven exposures which were affected by the moonlight are labelled with an asterisk and 30 m s\(^{-1}\) was quadratically added to their errors.

The sky area around CoRoT-10 (the brightest star near the centre). Left: R-filter image with a resolution of ∼ 2.5′′ taken with the OHP 1.20 m telescope. Right: image taken by CoRoT, at the same scale and orientation. The jagged outline in its centre is the photometric aperture mask; indicated are also CoRoT’s x and y image coordinates and position of nearby stars from the Exo-Dat database Deleuil et al. 2009.

Based on pre-launch observations stored in the Exo-Dat catalogue Deleuil et al. 2009, we estimated the flux contamination from the two faint background stars which fall inside the CoRoT-10 photometric mask to be 5.5±0.3% (see Fig. 5). We subtracted such a value from the median flux of the light curve (75559 e−/32 s), which makes the transits slightly deeper by ∼ 7·10^{-4} in relative flux. We then fitted a parabola to the 5 h intervals of the light curve before the ingress and after the egress of each transit in order to correct for any local variations. We disregarded two of the ten CoRoT-10b transits, precisely the second transit and the ninth, as their shape was deformed by hot pixels. Finally, we folded the light curve using the ephemeris reported in Table 4 and binning the data points in bins of 8·10^{-5} in phase, corresponding to ∼ 1.5 min (Fig. 7). The error on each bin was computed as the standard error of the data points inside the bin.

Transit best-fit was performed following the formalism of Giménez 2006, 2009 and fixing the eccentricity and the argument of the periastron to the values derived from the Keplerian fit of the radial velocity measurements (see Sect. 5.1). The four free parameters of the transit model are: the transit centre; the phase of the end of transit egress θ\(_{2}\) in the reference system for eccentric orbits defined by Giménez & García-Pelayo 1983 and shown in their Fig. 1 (see also Giménez 2009); the ratio of the planet to stellar radii k = R\(_p\)/R\(_∗\), and the inclination i between the orbital plane and the plane of the sky. The two non-linear limb-darkening coefficients u\(_1\) = u\(_{1r}\) + u\(_{1e}\) and u\(_2\) = u\(_{2r}\) − u\(_{2e}\) were fixed for two reasons: first, the relatively low signal-to-noise ratio of the transit light curve, which does not allow us to constrain either u\(_1\) or u\(_2\) within reasonable error bars; secondly, the degeneracy between the inclination and the two limb darkening coefficients in the case of a high impact parameter b, as in our case b = 0.85 ± 0.03 (see Table 4). The adopted limb-darkening coefficients u\(_{1r}\) and u\(_{1e}\) for the CoRoT bandpass were determined following the procedure in Sengupta & Giménez 2014. However, while the latter takes into account only the stellar emergent intensity for the values of μ ≥ 0.05, we considered all the 17 values available in the ATLAS model grids down to μ = 0.01. Our choice is motivated by the fact that the transit of CoRoT-10b is grazing, which implies that the variation of the specific intensity close to the limb of the stellar disc must be considered properly when modelling the transit shape. The derived limb-darkening quadratic coefficients are u\(_{1r}\) = 0.51 and u\(_{1e}\) = 0.21, which give u\(_{r}\) = 0.72 and u\(_{e}\) = 0.3.

The best-fit transit parameters were found by using the algorithm AMOEBA Press et al. 1992 and changing the initial values of the parameters with a Monte-Carlo method to find the global minimum of the χ\(^2\). Our best-fit of the phase-folded and binned transit light curve is shown in Fig. 7. Fitted and derived transit parameters are listed in Table 4 together with their 1-σ errors estimated using the bootstrap procedure described in Alonso et al. 2008a which takes also the correlated noise into account (cf. Alonso et al. 2008a, Sect. 3). Uncertainties on the eccentricity, the argument of the periastron and the contamination were also considered for the estimation of the errors of the derived transit parameters b, a/R\(_∗\), a/R\(_p\), M\(_p\)/R\(_∗\), R\(_p\), and ρ\(_p\), where b is the impact parameter, a the semi-major axis of the planetary orbit, R\(_p\) and M\(_p\), the stellar radius and mass, R\(_∗\) the planet radius, and ρ\(_p\) the stellar density (see Table 4).

The fitted value of the transit centre is consistent with zero within 1-σ, which confirms the good quality of the transit ephemeris (Sect. 5).

5. Stellar and planetary parameters

The spectral analysis of the parent star was performed with a high-resolution UVES spectrum acquired on the 30\(^{th}\) of July 2004. We used the Dic1 mode (390+580) and a slit width of 0.8′′, achieving a resolving power of ∼55 000. The total exposure time was 4 h leading to a signal-to-noise ratio per pixel S/N~120 at 5500 Å.

\(4\) u\(_1\) and u\(_2\) are the coefficients of the limb-darkening quadratic law: \(l(\mu)/l(1) = 1 - \mu u(1 - \mu) - u(1 - \mu)^2\), where l(1) is the specific intensity at the centre of the disk and μ = cos\(\gamma\), being the angle between the surface normal and the line of sight.

\(6\) UVES program ID: 083.C-0690(A)
Table 3. Abundances of some chemical elements for the fitted lines in the UVES spectrum. The abundances refer to the solar value and the last column reports the number of lines used.

| Element | Abundance | No. lines |
|---------|-----------|-----------|
| Ca I    | 0.21 ± 0.12 | 5         |
| Ti I    | 0.38 ± 0.11 | 15        |
| V I     | 0.63 ± 0.12 | 10        |
| Cr I    | 0.34 ± 0.13 | 7         |
| Fe I    | 0.26 ± 0.10 | 77        |
| Fe II   | 0.26 ± 0.11 | 5         |
| Co I    | 0.41 ± 0.10 | 7         |
| Ni I    | 0.35 ± 0.10 | 23        |
| Si I    | 0.37 ± 0.10 | 8         |

Saturated interstellar Na D lines in the HARPS spectra indicate a significant absorption along the line of sight. Converting the 2MASS J and K magnitudes (Table 1) in the Bessel & Brett photometric system, and comparing the (J - K) colour with that expected by Kurucz models for the CoRoT-10 spectral type and metallicity, we found a colour excess $E(J - K) \approx 0.24$. This corresponds to an extinction of $A_V \approx 1.39$ mag in agreement with reddening maps. Using the Pogson formula, the stellar distance was estimated to 345 ± 70 pc.

From the transit best-fit we derived a stellar density of $\rho_* = 3.32 \pm 0.70$ g cm$^{-3}$, i.e. $2.35 \pm 0.50 \rho_\odot$. CESAM and STAREVOL models of stellar evolution do not foresee any evolutionary track that matches the above-mentioned stellar density, given the effective temperature and the metallicity of CoRoT-10. Specifically, they predict an upper-limit of $2.55$ g cm$^{-3}$ ($1.79 \rho_\odot$), compatible at 1.1-sigma with the stellar density derived from the transit fitting. The mass and radius of the star provided by the CESAM evolutionary tracks are respectively equal to $M_* = 0.89 \pm 0.05 M_\odot$ and $R_* = 0.79 \pm 0.05 R_\odot$. The corresponding surface gravity, log $g$=4.59 ± 0.06 cm s$^{-2}$, is in good agreement with the spectroscopic value. The stellar age constraints are relatively weak but favor values smaller than 3 Gyr.

To derive the stellar atmospheric parameters, we first determined the $V\sin i_\star = 2 \pm 0.5$ km s$^{-1}$. To that purpose, we selected a few HARPS spectra that were not contaminated by the Moon reflected light. This series of spectra was set at rest and co-added. To carry out the detailed spectral analysis, we made use of the VWA software package and obtained: $T_{\text{eff}} = 5075 \pm 75$ K, log $g = 4.65 \pm 0.10$ cm s$^{-2}$ and $[\text{Fe/H}]= 0.26 \pm 0.07$ dex. The surface gravity value was checked with usual indicators: Na I D lines around 5890 Å, Mg I b lines, and Ca I lines at 6122, 6162 and 6439 Å. The abundances of several chemical elements are listed in Table 3. The elements for which we could only measure a few lines are not reported.

The absence of noticeable emission in the core of the Ca II H & K lines supports the low magnetic activity of CoRoT-10 indicated by its quiescent light curve (see Fig. 1).

Fig. 7. Top panel: Phase-folded light curve of 8 transits of CoRoT-10b. The bin size corresponds to 1.5 min and the 1-sigma error bars on each bin are estimated as the standard error of the data points inside the bin. The solid line shows our best-fit transit model. Bottom panel: the residuals from the best-fit model.
From the aforementioned stellar radius and mass, we determined the radius of the planet $R_p = 0.97 \pm 0.07 R_{\text{Jup}}$ and its mass $M_p = 2.75 \pm 0.16 M_{\text{Jup}}$. The bulk density, $\rho_p = 3.70 \pm 0.83 \text{ g cm}^{-3}$, is $\sim 2.8$ that of Jupiter.

### 6. Discussion and conclusions

We report the discovery of CoRoT-10b, a transiting planet on a highly eccentric orbit ($e = 0.53 \pm 0.04$) with a mass of $2.75 \pm 0.16 M_{\text{Jup}}$ and a radius of $0.97 \pm 0.07 R_{\text{Jup}}$. It orbits a metal rich ([Fe/H] = 0.26 ± 0.07) K1V star with a visual magnitude $V = 15.22$ in 13.24 days. Fig. 8 shows the position of CoRoT-10b in the eccentricity-period diagram of the known extrasolar planets and highlights its peculiarity as it belongs to the class of the few transiting exoplanets with highly eccentric orbits ($e \geq 0.5$) among which HAT-P-2b, HD 17156b and HD 80606b.

To investigate the internal structure of CoRoT-10b, we computed planetary evolution models with CEPAM (Guillot & Morel 1995) under the standard hypothesis that the planet is made up of a central rocky core of variable mass and of an overlying envelope of solar composition (e.g., Guillot 2008). The results in terms of planetary size as a function of system age are shown in Fig. 9. The coloured regions (red, blue, yellow-green) indicate the constraints derived from the stellar evolution models at 1, 2 and 3 $\sigma$ level, respectively. Assuming a zero Bond albedo, we derived the equilibrium temperature of the planet $T_{eq} = 600$ K. For this temperature, models of planet internal structure with a core mass of 0, 20, 60, 120, 180, 240 and 320 $M_\oplus$ were computed (Fig. 9). Note that a 25% change in the equilibrium temperature yields a difference in the resulting planetary radius of less than 1%. Therefore, a Bond albedo considerably different from zero (up to $A_B \approx 0.7$) does not change significantly our results.

CoRoT-10b is a high density planet with a mass and density similar to those of HD 17156b (Barbieri et al. 2009) but with a higher content of heavy elements. For an age of the star and hence of the planetary system between 1 and 3 Gyr, CoRoT-10b should contain between 120 and 240 $M_\oplus$ of rocks in its interior (i.e. between 14 and 28% of the total mass), at 1-sigma level. Mixing heavy elements in the envelope rather than assuming that they are all contained in the core may yield a reduction of these numbers by $\sim 30\%$ (Baraffe et al. 2008). This number is uncertain however because it does not account for the increase in opacity in the outer radiative zone that would have the opposite effect (Guillot 2003). In any case, CoRoT-10b is found to be extremely enriched in heavy elements, suggesting that its formation probably required giant collisions (see Ikoma et al. 2006). It also strengthens the observed correlation between star metallicity and heavy elements in the planet (Guillot 2008).

Moving along its eccentric orbit from the apoastron to the periastron, CoRoT-10b experiences a 10.6-fold variation in insolation. Moreover, since the tidal interaction with the parent star is strongest around periastron, the planet is expected to be in pseudo-synchronous rotation. Eq. 42 from Hut (1981) gives a rotation period of the planet $P_{\text{rot}} = 4.25 \pm 0.53$ days. Time-dependent radiative models of planetary atmospheres could be used to study heating variations due to the changing star-planet distance at different pressure levels of the planet atmosphere and to predict temperature inversions caused by strong heating around periastron, as done by Iro & Deming (2010) for HD 17156b and HD 80606b.

Using Eq. 6 in Matsumura et al. (2008), we can estimate the circularisation time $\tau_{\text{circ}}$ of the planetary orbit, neglecting the stellar damping. The circularisation time strongly depends on the adopted tidal quality factor for the planet $Q_p$, which is not well known. For Jupiter, $5 \cdot 10^4 < Q_p < 2 \cdot 10^6$ (Yoder & Peale 1983; Lainey et al. 2009) and for most of the giant extrasolar planets $10^3 < Q_p < 10^5$ (see Fig. 2 from Matsumura et al. 2008). Considering $Q_p = 10^5$, we find $\tau_{\text{circ}} \approx 7.4$ Gyr. Owing to the long circularisation time, the eccentricity of CoRoT-10b need not be excited and maintained by the resonant interaction with...
another planet. Nevertheless, the eccentric orbits of extrasolar planets can be explained by gravitational planet–planet scattering (e.g., Chatterjee et al. 2008 and references therein). If another massive planet survived the violent encounters between planets and is currently orbiting around the parent star, it could be detected by a long-term radial velocity follow-up of the parent star, e.g., showing a long-term drift induced by the distant companion. If the star has a distant companion of stellar nature, the high eccentricity of CoRoT-10b could be produced by Kozai oscillations rather than planet–planet scattering (e.g., Takeda & Rasio 2005). Distinguishing between the two scenarios would make us understand the dynamical evolution of the eccentric giant planet CoRoT-10b.

Acknowledgements. The authors wish to thank the staff at ESO La Silla Observatory for their support and for their contribution to the success of the HARPS project and operation. The team at IAC acknowledges support by grant ESP2007-65480-C02-02 of the Spanish Ministerio de Ciencia e Innovación. The CoRoT/Exoplanet catalogue (Exodat) was made possible by observations collected for years at the Isaac Newton Telescope (INT), operated on the island of La Palma by the Isaac Newton group in the Spanish Observatorio del Roque de Los Muchachos of the Instituto de Astrofisica de Canarias. The German CoRoT team (TLS and University of Cologne) acknowledges DLR grants 50OW0204, 50OW0603, and 50QP0701. The French team wish to thank the Programme National de Planétologie (PNP) of CNRS/INSU and the French National Research Agency (ANR-08-JCJC-0102-01) for their continuous support to our planet search. The Swiss team acknowledges the ESA PRODEX program and the Swiss National Science Foundation for their continuous support on CoRoT ground follow-up. A. S. Bonomo acknowledges CNRS/CNES grant 07/0879-Corot. S. Aigrain acknowledges STFC grant ST/G002266. M. Gillon acknowledges support from the Belgian Science Policy Office in the form of a Return Grant.

### Table 4. Planet and star parameters.

| Ephemeris                                                                 |            |
|--------------------------------------------------------------------------|------------|
| Planet orbital period $P$ [days]                                         | 13.2406 ± 0.0002 |
| Planetary transit epoch $T_0$ [HJD-2400000]                              | 54273.3436 ± 0.0012 |
| Planetary transit duration $d_v$ [h]                                     | 2.98 ± 0.06 |
| Planetary occultation epoch $T_{oc}$ [HJD-2400000]                      | 54276.49 ± 0.41 |
| Planetary occultation duration $d_{oc}$ [h]                             | 2.08 ± 0.18 |
| Epoch of periastron $T_0$ [HJD-2400000]                                 | 54990.85 ± 0.08 |

| Derived parameters from radial velocity observations                   |            |
|------------------------------------------------------------------------|------------|
| Orbital eccentricity $e$                                               | 0.53 ± 0.04 |
| Argument of periastron $\omega$ [deg]                                  | 218.9 ± 6.4 |
| Radial velocity semi-amplitude $K$ [m s$^{-1}$]                         | 301 ± 10    |
| Systemic velocity $V_s$ [km s$^{-1}$]                                  | 15.33 ± 0.007 |
| O-C residuals [m s$^{-1}$]                                             | 29         |

| Fitted and fixed transit parameters                                    |            |
|------------------------------------------------------------------------|------------|
| $\theta_e$                                                             | 0.00483 ± 0.00009 |
| Radius ratio $k = R_p/R_*$                                              | 0.1269 ± 0.0038 |
| Inclination $i$ [deg]                                                   | 88.55 ± 0.2 |
| $u_+$ (fixed)                                                           | +0.072     |
| $u_-$ (fixed)                                                           | +0.30      |

| Derived transit parameters                                             |            |
|------------------------------------------------------------------------|------------|
| $a/R_*$                                                                | 31.33 ± 2.15 |
| $a/R_p$                                                                | 247 ± 21   |
| $(M_p/M_*)^{1/3}(R_p/R_*)^{-1}$                                        | 1.33 ± 0.09 |
| Stellar density $\rho_*$ [g cm$^{-3}$]                                  | 3.32 ± 0.70 |
| Impact parameter $b$                                                    | 0.85 ± 0.03 |

| Spectroscopic parameters of the star                                    |            |
|------------------------------------------------------------------------|------------|
| Effective temperature $T_{\text{eff}}$ [K]                            | 5075 ± 75  |
| Surface gravity log $g$ [cgs]                                          | 4.65 ± 0.10|
| Metallicity [Fe/H] [dex]                                               | +0.26 ± 0.07 |
| Stellar rotational velocity $V \sin i$ [km s$^{-1}$]                   | 2.0 ± 0.5  |
| Spectral type                                                          | K1V        |

| Stellar and planetary physical parameters                              |            |
|------------------------------------------------------------------------|------------|
| Star mass $(M_*)$ [M$_\odot$]                                          | 0.89 ± 0.05 |
| Star radius $(R_*)$ [R$_\odot$]                                        | 0.79 ± 0.05 |
| Planet mass $(M_p)$ [M$_{\oplus}$]                                     | 2.75 ± 0.16 |
| Planet radius $(R_p)$ [R$_{\oplus}$]                                   | 0.97 ± 0.07 |
| Planet density $\rho_p$ [g cm$^{-3}$]                                  | 3.70 ± 0.83 |
| Planet surface gravity log $g_p$ [cgs]                                 | 3.93 ± 0.08 |
| Planet rotation period $P_{\text{rot}}$ [days]                         | 4.25 ± 0.53 |
| Distance of the star $d$ [pc]                                           | 345 ± 70   |
| Orbital semi-major axis $a$ [AU]                                        | 0.1055 ± 0.0021 |
| Orbital distance at periastron $d_{\text{per}}$ [AU]                   | 0.0496 ± 0.0039 |
| Orbital distance at apostron $d_{\text{apo}}$ [AU]                     | 0.1614 ± 0.0047 |
| Equilibrium temperature at the averaged distance $T_{\text{eq}}$ [K]   | 600 ± 23   |
| Equilibrium temperature at periastron $T_{\text{eq}}^{\text{peri}}$ [K]| 935 ± 54   |
| Equilibrium temperature at apostron $T_{\text{eq}}^{\text{apo}}$ [K]  | 518 ± 20   |
