Abstract
We report about a 61-year-old man who, 6 years after initial uncomplicated mitral valve repair and 3 months after treatment of a pseudo-aneurysm of the ascending aorta with a Dacron patch, was admitted in our institution with an infection of the vascular graft, which was associated with sternal osteomyelitis and purulent cutaneous fistula. In a re-redo procedure, the proximal aortic arch and the ascending aorta were replaced with a cryopreserved aortic homograft. The infected part of the sternum was resected and the defect was covered by mobilizing the mediastinal tissue and with a bilateral muscle flap. The patient was discharged 20 days after surgery. This treatment concept outlines the benefit of cryopreserved aortic homograft when faced with a complex thoracic aortic infection.

INTRODUCTION
Sternal osteomyelitis combined with an infection of a vascular graft is a serious complication following open-heart surgery, with high mortality rates. In these cases, the explanation of the infected graft is the recommended treatment. Cryopreserved arterial homografts are very resistant against infection and offer good long-term results in cases of infection of either native arteries or prosthetic grafts. We present a rare case of sternal osteomyelitis, combined with a cutaneco-mediastinal fistula path, and consequently, infection of a vascular graft as a very late complication after open-heart surgery.
and the cartilage to the second left rib were completely resected. The rib was then fixated to the right side of the sternum using a titanium plate. The remaining sternum was treated with antiseptic solution and was then conventionally closed with sternal wires. The pectoralis major was mobilized on both sides together with the skin and was used to stabilize the wound.

The post-operative course was uneventful and the patient was discharged 20 days after surgery.

The histological analysis confirmed different stages of infection and inflammation of the resected aorta. Pseudomonas aeruginosa was cultivated from the intra-operative cultures. The patient received a combination of three antibiotics for 7 days, followed by single gentamicin treatment for another 10 days. The scar healed without any signs of inflammation. The control CT scan showed good consolidation of the sternum with no signs of infection (Fig. 3).

At his follow-up visit after 6 months, and again 5 years after surgery, the patient was completely restored into normal life and the sternal wound was perfectly healed.

**DISCUSSION**

Sternocutaneous fistulas are rare, but since they may have a devastating course, increased awareness of this infectious complication after open-heart surgery is important [1]. Moreover, sternal osteomyelitis combined with an infection of a vascular graft is a life threatening complication. *Staphylococcus aureus* is the most frequent organism found after coronary artery bypass grafting surgery. *Candida* species and gram-negative bacteria are more common after heart or heart–lung transplantation. *Pseudomonas aeruginosa* has been rarely reported [2].

Complete resection of the infected foreign material and of the affected aorta with debridement of the surrounding tissue, followed by antibiotic treatment, gives most probably the best results. An orthotopic reconstruction is the best option for all thoracic and thoraco-abdominal pathologies, and the use of coated prostheses, homografts or self-made vascular tubes from xenopericardial tissue has to be discussed from case to case [3]. The use of cryopreserved homografts is related to low reinfection rates and decreased early and midterm mortality, especially when aggressive debridement has been undertaken [4, 5].

The use of pedicled myocutaneous or muscle flaps without sternal resection and/or omental transposition has proved to be an effective and reliable method for the management of patients with complicated cardiothoracic problems [1, 6–11]. In our case, the described sternal reconstruction technique in combination with antibiotic treatment proved to be an additional option for the successful management of advanced sternal osteomyelitis.
CONSENT
Written informed consent was obtained from the patient for the publication of this case report and any accompanying images.

CONFLICT OF INTEREST STATEMENT
None declared.

FUNDING
None.

AUTHORS’ CONTRIBUTIONS
All authors participated in the design of the case report and coordination and helped to draft the manuscript. All authors read and approved the final manuscript.
