Libertín, M., Kvaček, J., Bek, J., Štorch, P. (2018): Plant diversity of the mid Silurian (lower Wenlock, Sheinwoodian) terrestrial vegetation preserved in marine sediments from the Barrandian area, the Czech Republic. – Fossil Imprint, 74(3-4): 327–333, Praha. ISSN 2533-4050 (print), ISSN 2533-4069 (on-line).

Abstract: Plant mega- and microfossils are described from the middle Sheinwoodian of the Barrandian area. The material comes from the Loděnice locality and the same horizon as the earliest unequivocal land plant, Cooksonia barrandei Libertín, J.Kvaček, Bek, Žárský et Štorch. Its age (432 Myr) is inferred from the associated graptolite fauna, including the zonal index graptolite Monograptus belophorus. Megafossils have clear similarity with Cooksonia, due to their dichotomised axes with slightly widened subtending axes bearing putative sporangia. They document some of the plant diversity that was in place when the first proven representative of the genus Cooksonia appeared, and together with dispersed spores they provide strong and important evidence that a diversified terrestrial ecosystem had developed on the Barrandian volcanic archipelago in the peri-Gondwanan realm by the end of the Sheinwoodian Stage of the Silurian Period.

Introduction

Early land plants found in the Silurian marine sediments of the Barrandian area of central Bohemia (the Czech Republic) have been a recent focus of Czech palaeobotanists (Kraft and Kvaček 2017, Kraft et al. 2018, Libertin et al. 2018). The latter publication is of particular importance because it documents Cooksonia barrandei Libertín, J.Kvaček, Bek, Žárský et Štorch in sediments dated to about 432 Myr, making it the earliest megafossil polysporangiate land plant (Libertin et al. 2018). It is of particular interest that the next oldest evidence of polysporangiate land plants comes from sediments approximately 5 Myr younger (Homarian Stage) in Ireland (Edwards et al. 1983). Most of the early land plants are referred to as cooksonioids (e.g. Taylor et al. 2009), and they are characterized by very small size. This particular feature led Boyce (2008) to hypothesize that their life cycle was similar to that of modern bryophytes, however this was questioned by Libertin et al. (2018), who used large size of C. barrandei as one of the major counter-arguments.

Here we document dichotomizing plant fossil remains some of which have putative sporangia attached. The fossils come from the same locality as C. barrandei, Loděnice in the Barrandian area of the Czech Republic (Text-fig. 1a, b), and they provide evidence of additional plant diversity at a very early stage of vascular plant evolution.

Material and methods

The fossils consist of the type material of Cooksonia barrandei and three more fertile specimens from the Loděnice locality, the most important specimens come from the historical collection of Joachim Barrande (1799 – 1883) who identified them as marine algae (Fucoides) in accordance with understanding of the material at the time and thus seemingly uninteresting. The material was re-discovered in 2012 by Vojtěch Turek of the National Museum, Prague, while moving the collection to the museum’s new repository building. The best-preserved specimens, very probably fertile cooksonioid plants, are described here, and they bear characters that distinguish them from C. barrandei. In several cases fragments of Cooksonia were found on the same bedding plane as the
graptolite Monograptus belophorus (MENEGHINI) = M. flexilis ELLES. This fact, together with similarities in lithology and associated trilobite and shell-bearing fauna occurring on the bedding plane of the samples in this rediscovered box, led us to infer that the approximately 50 cooksonioid specimens, including the type material of C. barrandei, came from the Monograptus belophorus Biozone.

We relocated the original locality where Barrande collected the specimens of C. barrandei and all the present material we examined here including three other fertile
specimens. Eleven sterile fragments of cooksonioids have been newly collected from the brown-grey calcareous and tuffaceous shale of the belophorus Biozone of the Motol Formation that is exposed near to Barrande’s original locality (Text-fig. 1b). However, none of them is as completely preserved as the historical specimens.

The layer with Cooksonia fossils contains a diverse marine fauna. Besides Monograptus belophorus, other stratigraphically important graptolites, including Monograptus flemingii (SALTER), Monoclimacis meneghinii (GORTANI), Mediograptus antennarius (MENEGHINI), Pristiograptus ?dubius dubius (SUSS), Paraplectograptus sp., the trilobite Miraspis mira (BARRANDE), and other taxa allow us to assign this unit to the internationally recognised belophorus Biozone (Štorch 1994, Loydell 2012) of the middle Sheinwoodian Stage of the Wenlock Series (Text-fig. 2). This fauna, which includes diverse trilobites and brachiopods, has been assigned to the Miraspis trilobite Assemblage by Chlupáč (1987) or the Miraspis-Mezoaonia bentic community by Havlíček and Štorch (1990). This bottom-dwelling fauna inhabited a quiet, well-oxygenated environment in a photic zone below storm-wave base. Layer 4 (Text-fig. 1c), where the cooksonioids were found, consists of fine-grained laminated calcareous and tuffaceous shales; layer 5 comprises tuffaceous shales with limestone intercalations. All sediments in this profile (Text-fig. 1c) originated in a moderately shallow, quiet-water environment surrounding a volcanic island the source of our plant specimens. The central part of the island was estimated as about 2 km from the studied outcrop (Horny 1962, Kříž 1991, 1992, Chlupáč et al. 1998). The distribution of tuffaceous and calcareous components in these sediments was governed by the intensity of volcanic activity (Chlupáč et al. 1998) and the distance from the volcanic centre; particles of various densities precipitated out in the water column at different distances from volcanic vents (Text-fig. 1b).

Plant fossils were studied and documented using an Olympus SZX-12 binocular microscope equipped with a DP-72 digital camera. Specimens were photographed immersed in alcohol under diffusely polarised light using a Canon EOS 50D digital camera equipped with a Sigma Macro 50 lens and circular polarizer filter. The reconstruction of Cooksonia barrandei was done by Jiří Žárský.

Dispersed and in situ spores were macerated using hydrochloric acid (24 hours), hydrofluoric acid (5 days), hydrofluoric acid (15 minutes), potassium hydroxide (15 minutes) and washed by water several times. Palynological slides were prepared using a glycerine jelly mounting medium. Plant microfossils were studied and documented using a NIKON BX51 light microscope.

Preparation of cuticles was extremely difficult and none of them provided details informative enough to be published. The preparations were studied using an Olympus BX 50 microscope. Plants were also observed in low-vacuum mode of the Hitachi S-3700N SEM, but cellular details (e.g. conducting tissues) were not observed.

All the studied material is housed in the collections of the National Museum, Prague (NM).

Systematic palaeobotany

Cooksonia barrandei Liberti, J.KVAČEK, BEK, ŽÁRSKÝ ET ŠTORCH

Text-fig. 3a, b

Holotype. NM-D 552a, b, National Museum, Prague (Text-fig. 3a).

Type locality. Loděnice, Špičatý vrch – Barrandovy Jámy.
Type horizon. *Monograptus belophorus* Biozone, Motol Formation, middle Sheinwoodian, Wenlock, Silurian.

Remarks. For diagnosis, description, and spores in situ see Libertín et al. (2018). However, some details, particularly related to the handwritten notes, were not mentioned in the paper referred to above. Both part and counterpart of the holotype bear the name of the locality handwritten in black ink directly on the rock by Joachim Barrande. The handwritten note is as follows: Lodenitz (E). The letter E indicates Barrande’s labeling of the Silurian section as depicted in his diary (Text-fig. 4). This letter on the type specimen, together with associated zonal index graptolite *Monograptus belophorus* (MENEGHINI), helped the authors to identify the source horizon of the type material.

Additionally, we present here an idealized reconstruction of *C. barrandei* showing an overtopped terminal part of the axis and curved, probably creeping main axis. This reconstruction was prepared in collaboration with an artist Jiří Svoboda (Text-fig. 3b).

**Cooksonia sp.**

Text-fig. 5a–c

**Cooksonia sp.**

Text-fig. 5a–c

Locality. Loděnice, Špičatý vrch – Barrandovy Jámy.

Horizon. *Monograptus belophorus* Biozone, Motol Formation, middle Sheinwoodian, Wenlock, Silurian.

Material. Specimens, NM-D 550, NM-D 554, NM-D 557a, b, National Museum, Prague.
**Description.** The largest specimen (NM-D 554) is 75 mm long and 3.2 mm broad in its basal part (Text-fig. 5a). Its axes are three times isotomously branched. In the lower proximal branches, one branch subsequently becomes dominant. This means that the branches are isotomous with overtopping. They do not form a pseudomonopodium, because branches of higher orders are uniform. Branching is comparatively regular; segments branch off at acute angles of 30° to 40°, and range from 7 mm to 25 mm in length (Text-fig. 5a). The sporangium (3 mm in diameter) is loosely attached (attachment being visible only in polarized light Text-fig. 5a).

There are two further specimens (NM-D 550, NM-D 557a, b; Text-fig. 5b, c) showing putative terminally-borne sporangia (3–3.8 mm in diameter). The specimens are branched isotomously three times, with overtopping. The precise mode of attachment of sporangia is obscured by the sporangia themselves covering critical areas. Specimen NM-D 550 shows a 25 mm long terminal axis. Sporangia are well-preserved in its left part. Specimen NM-D 557a and its counterpart NM-D 557b show several putative sporangia forming one group, loosely attached and of moderate preservation. The axis has the same general form as NM-D550 and NM-D554.

**Discussion.** The above described fossil plant material identified as *Cooksonia* sp. differs from *Cooksonia barrandei* (Libertín et al. 2018) in having upright axes and slender terminal parts of subtending axes and sporangia without a rim. Additionally, terminal parts of *Cooksonia* sp. branches are shorter than *C. barrandei*, and their branching is more frequent.
The specimens described by Libertín et al. (2002) resemble *Cooksonia* sp. rather than *C. barrandei* in the absence of an apparently procumbent basal part of its axis and having terminal axes only slightly widened without any pronounced sporangial rim. *C. bohemica* differs from *Cooksonia* sp. in having a wider branching angle, short subtending axes and kidney-shaped sporangia (Schweitzer 1980).

*Cooksonia* sp. also resembles *Concavatheca banksii* from the Lochkovian of England (Habgood et al. 2002, Morris et al. 2012) in having similarly shaped terminal axes subtending sporangia. According to Morris et al. (2012), *Concavatheca* differs from *Cooksonia* in having, “extension of the sporangial cavity into the distally widening subtending axis as exemplified by changes in the shape of the epidermal cells”. This character is not possible to distinguish in our material, although the shapes of subtending axes of both *Concavatheca banksii* and *Cooksonia* sp. are similar. The holotype of *Concavatheca banksii* is a charcoalfied mesofossil, while our material consists of compressions. Due to different preservation states of the two species, direct and detailed comparisons cannot be made. However, there are more distinguishing characters between the above mentioned taxa, particularly in sizes of their axes and sporangia. Three subspecies of *Cooksonia pertoni* (*C. pertoni* sp. *pertoni*, *C. pertoni* sp. *synorispora* from Pridoli (Fanning et al. 1988) and *C. pertoni* sp. *reticulospora* from Lochkovian (Habgood et al. 2002)) described from Great Britain differ from *Cooksonia* sp. particularly in their smaller size. *Cooksonia hemisphaerica* from the Lochkovian of England (Lang 1937), recorded also from the Pridoli Series of the Barrandian area (Obrhel 1962), differs from *Cooksonia* sp. in both its size and in the shape of the sporangia, which are hemispherical. *Cooksonia* sp. differs from *Cooksonia crassiparietilis* from the Early Devonian of Kazakhstan (Yurina 1969) in having a wider branching angle (60°) and more elliptically shaped sporangia. *Cooksonia* sp. from the uppermost Homerian of Tipperary in Ireland (Edwards et al. 1983) differs from our material in size; their axes are only about 0.2 mm in diameter and having slightly widened axes subtending sporangia (Morris et al. 2012).

The dispersed spore assemblage prepared from the same sediment samples bearing *Cooksonia* fossils provided at least five other trilete spore types, suggesting further diversity of coxsonioid and similar plants. The dispersed spores will be described in a separate paper.

The *Cooksonia* fossils described here come from what was then the southern hemisphere, where the peri-Gondwana terranes and microcontinents, including those of the present Bohemian Massif, were situated at mid latitude (Cocks and Torsvik 2006). The rocks containing these fossils are products of near-shore marine sedimentation associated with volcanic islands, the largest of which formed today’s Svatý Jan Volcanic Centre (Havlíček and Štorch 1990, Kříž 1991).

Conclusions

Material documented here records the extent of the currently known plant diversity associated with *Cooksonia barrandei* during the middle Shinwoodian Stage (ca. 432 Myr) of the Silurian Period. Megafossils are attributable to *Cooksonia* sp., and five taxa of dispersed spores derived from at least five different plants. Additionally, the first reconstruction of *Cooksonia barrandei* is presented to the broader public. These fossils support the existence of a relatively diverse terrestrial flora in the volcanic archipelago of the Barrandian area, which at this time was situated on the northern margin of the supercontinent of Gondwana.

Acknowledgements

We are grateful to all three reviewers Dianne Edwards (Cardiff University), Paul Kenrick (Natural History Museum, London), Charles Wellman (The University of Sheffield), for their critical comments and suggestions. Financial support from the Grant Agency of Czech Republic, First vascular land plants and palynomorphs from the Silurian-Lower Devonian of the Barrandian area, Czech Republic (GAČR 17-10233S) is acknowledged. Part of this contribution was also supported by the Research Program of the Institute of Geology CAS, v.v.i. (RVO67985831).
