Abstract: Fatty acid β-oxidation (FAO) and oxidative phosphorylation (OXPHOS) are mitochondrial redox pathways that generate ATP. The biogenesis of the respiratory Complex I, a 1 MDa multiprotein complex that is responsible for initiating OXPHOS, is mediated by assembly factors including the mitochondrial complex I assembly (MCIA) complex. However, the organisation and the role of the MCIA complex are still unclear. Here we show that ECSIT functions as the bridging node of the MCIA core complex. Furthermore, cryo-electron microscopy together with biochemical and biophysical experiments reveal that the C-terminal domain of ECSIT directly binds to the vestigial dehydrogenase domain of the FAO enzyme ACAD9 and induces its deflavination, switching ACAD9 from its role in FAO to an MCIA factor. These findings provide the structural basis for the MCIA complex architecture and suggest a unique molecular mechanism for coordinating the regulation of the FAO and OXPHOS pathways to ensure an efficient energy production.

Introduction

Mitochondria coordinate central functions in the cell and have a crucial role in energy metabolism. Fatty acid β-oxidation (FAO) and oxidative phosphorylation (OXPHOS) are mitochondrial enzymatic pathways responsible for coupling redox reactions to ATP production. The OXPHOS system, composed of the respiratory chain components embedded in the mitochondrial inner membrane, includes five multimeric enzymes, the first of which is Complex I (CI or NADH:ubiquinone oxidoreductase). The redox reactions involved in ATP production generate reactive oxygen species (ROS), which have important roles in cell signalling and homeostasis but also cause oxidative damage to DNA, lipids and proteins including those in the respiratory chain itself. As the first enzyme of the respiratory chain, CI is the main source and target of ROS and deficiencies in CI activity, which are often characterized by defects in the CI assembly process, lead to the most common OXPHOS disorders in humans. Mammalian CI is the largest (~1 MDa) membrane protein complex, composed of 44 different subunits encoded by the nuclear and the mitochondrial genome. While the atomic structure of CI is known, the mechanisms of CI biogenesis involving the coordinated assembly of intermediate modules and insertion of cofactors to form a functional complex remain elusive. CI biogenesis is assisted by assembly factors that ultimately dissociate from the final holoenzyme.

The mitochondrial CI assembly (MCIA) complex has been recently described and is believed to participate in the assembly of early CI intermediate modules. The MCIA complex itself is composed of three core subunits—NDUFAF1, ACAD9 and ECSIT—which seem to further associate

Supporting information (SAXS data were deposited into SASDB database (IDs: SASDHU4; SASDHV4; SASDHW4; SASDHY4; SASDHY4 and SASDHZ4); the cryo-EM map of the ACAD9-ECSIT complex was deposited into the EMDB data bank (ID: EMDB120551)) and the ORCID identification number(s) for the author(s) of this article can be found under: https://doi.org/10.1002/anie.202011548.
with other membrane proteins such as TMEM126B, TIMMDC1, TMEM186 and COA1. Knockdown of any of the core MCIA proteins in cultured cells leads to decreased levels of the other two partners and results in impaired CI assembly and activity. However, the molecular details underlying the activity of the MCIA complex are unclear, partly because as well as participating in CI maturation, the individual components of the MCIA complex are also involved in other cellular functions. Here, ECSIT, which is predicted to contain an ordered N-terminal domain followed by a disordered C-terminal region, was initially identified as a cytoplasmic and nuclear signalling protein while ACAD9 was annotated as an acyl-CoA dehydrogenase (ACAD) enzyme due to its sequence homology with the very long chain acyl-CoA dehydrogenase VLCAD, which initiates the FAO pathway with the concurrent reduction of its FAD cofactor. Although the biological relevance of ACAD9 function as a FAO enzyme has been controversial, recent findings suggest physical interactions between FOA and OXPHOS proteins. Molecular insights into the protein interactions linking these two pathways are thus crucial for understanding the pathogenesis of diseases entailing OXPHOS and FAO deficiencies, such as Alzheimer’s disease (AD), with considerable evidence indicating a strong association between CI activity and amyloid-beta (Aβ) toxicity. Noteworthy, ECSIT has been identified as a molecular node interacting with enzymes producing Aβ, implying a potential role in AD pathogenesis.

In this study, we provide the molecular characterisation of ECSIT as an interacting node of the MCIA complex together with the 3D architecture of C-terminal ECSIT with ACAD9. We also report a novel delavination mechanism mediated by ECSIT that antagonises ACAD9 enzymatic activity, switching ACAD9 from a role as an FAO enzyme to a CI assembly factor. Taken together, our results provide insights into MCIA complex biogenesis and suggest a possible mechanism for coordinating the regulation between OXPHOS and FAO protein complexes to ensure an efficient energy production.

Results

ECSIT is the bridging component of the MCIA complex

We examined the interactions between three MCIA complex core components NDUF AF1, ACAD9 and ECSIT in cellulo by yeast two-hybrid (Y2H) (Figure 1A) and mammalian cell bimolecular fluorescence complementation (BiFC) (Figure 1B,C) assays. While mitochondrial ECSIT (residues 49–431), as well as individual N- and C-terminal fragments (ECSITN-terminal and ECSITC-terminal respectively, described below) were found to associate with NDUF AF1 (Figure 1A), only ECSITC-terminal showed interaction with ACAD9 (Figure 1B,C). No direct interaction between NDUF AF1 and ACAD9 was observed (Figure 1A), as confirmed by in vitro interaction analysis with recombinant purified proteins (Figure 1D).

The above observations suggest that ECSIT carries independent interaction sites for NDUF AF1 and ACAD9 (Figure 1E). We therefore attempted to further examine the interaction of ECSIT with either ACAD9 or NDUF AF1. Here, the tendency of mitochondrial ECSIT purified from recombinant bacteria to form soluble aggregates (Figure S1) motivated us to apply ESPRIT (Expression of Soluble Proteins by Random Incremental Truncation) technology in order to identify soluble and monodisperse ECSIT fragments (Figure S2). Whereas all N-terminal fragments were insoluble, a C-terminal fragment (ECSITC-terminal, residues 248–431) showed high expression and solubility (Figure S2).

Interestingly, this fragment corresponds to the isofrom ECSIT-3, an alternative splicing variant that has been observed at the transcript level. Analyses of purified ECSITC-terminal both by size-exclusion chromatography (SEC) coupled to multi-angle laser light scattering (SEC-MALLS) (Figure S3) and by small-angle X-ray scattering (SAXS) (Figure S4A, Table S1) yielded an approximate molecular mass of 46 kDa, suggesting that ECSITC-terminal is predominantly a dimer in solution. SAXS and 2D NMR data (Figure S4A, B) indicated that these dimers are elongated and only partially folded, consistent with the prediction of a highly disordered domain. Native mass spectrometry (native MS) confirmed that ECSITC-terminal forms dimers and revealed that these may further associate into tetramers and higher-order multimers (Figure S4C).

Purified mature NDUF AF1 (residues 25–327) behaved as a monodisperse monomer in SEC-MALLS and SAXS experiments (Figure S3, Table S1) whereas, in agreement with a previous study, recombinant, purified ACAD9 (residues 38–621) was detected as a monodisperse homodimer by SEC-MALLS (Figure S3). Negative-stain electron microscopy (ns-EM) (Figure S5A, B) and SAXS analysis (Figure S5B, Table S1) of ACAD9 revealed compact, rectangular envelopes (Figure S5A) consistent with a previously reported homology model of the ACAD9 dimer. This model is based on the crystal structure of VLCAD, with which ACAD9 shares 47% sequence identity (Figure S5C). Notably, SEC-MALLS highlighted that VLCAD and ACAD9 share similar molecular weights but different elution profiles (Figure S5C), suggesting that ACAD9 occupies a larger hydrodynamic volume. A SAXS structural comparison confirmed that VLCAD folds into a more close-packed conformation in solution (Figure S5D, Table S1).

ECSITC-terminal forms a stable complex with ACAD9

In contrast to the interaction observed by Y2H (Figure 1A), ECSITC-terminal did not bind NDUF AF1 in electrophoretic mobility shift assays (Figure S6A), suggesting that the N-terminal domain of ECSIT is required for a high-affinity interaction with NDUF AF1. Conversely, we were able to reconstitute a complex between ECSITC-terminal and ACAD9 (ACAD9-ECSITC-terminal) in vitro that remained stably associated during SEC (Figure 2A) and electrophoretic mobility shift assays (Figure S6B). Moreover, differential scanning calorimetry experiments showed that the presence of ECSITC-terminal (which has a poorly defined melting profile) enhanced the thermostability of ACAD9 by >15°C (Figure 2C).
The stability of the ACAD9-ECSIT CTD interaction was further confirmed by the protection of ACAD9 from proteolytic cleavage upon ECSIT CTD binding (Figure 2F). However, SANS analysis revealed a large molecular volume for the ACAD9-ECSIT CTD complex, implying a dynamic assembly process (Figure 2B). Consistent with this finding, NMR analysis of 15N-labelled ECSIT CTD showed that the domain’s random coil region remains largely unperturbed upon the addition of ACAD9, although a number of shift perturbations in the HSQC spectrum (Figure 2D,E) suggests that ACAD9 interacts with specific residues within the ECSIT CTD fragment. NDUFAF1 was unable to co-elute with the ACAD9-ECSIT CTD complex (Figure S6C), consistent with the earlier observation that the N-terminal domain of ECSIT is required for a high-affinity interaction with NDUFAF1.

**Cryo-EM analysis of the ACAD9-ECSIT CTD complex**

We next investigated the structure of the ACAD9-ECSIT CTD complex by cryo-electron microscopy (cryo-EM)
Analysis of the 2D class averages (Figure 2G) showed a strongly preferred orientation and revealed that the complex possesses a defined core with visible secondary structural features. While this core clearly corresponds to the ACAD9 dimer, consistent with the ns-EM map (Figure S5B), some classes also show diffuse densities at the periphery of this core (Figure 2G, white arrows), which we tentatively attribute to the largely unfolded parts of ECSIT<sub>CTD</sub>. A standard image processing procedure aimed for higher resolution reconstruction would result in masking out these peripheral densities while focusing on the compact core. Here however, we first chose not to use a mask in order to obtain low resolution information on the global shape of the ACAD9-ECSIT<sub>CTD</sub> complex and define the ECSIT<sub>CTD</sub> binding site. Comparison of the resulting 3D reconstruction with the ns-EM map and the VLCAD-based homology model of ACAD9 suggests that the extra densities that protrude out of the central ACAD9 dimer core may correspond to ordered segments of ECSIT<sub>CTD</sub>. The fact that only a small proportion of the bound ECSIT<sub>CTD</sub> is visible in the cryo-EM density is compatible with the NMR data (Figure 2D), indicating that the disorder of ECSIT<sub>CTD</sub> is mostly retained upon ACAD9 binding. Analysis of the sample used for cryo-EM by native MS confirmed the presence of ECSIT<sub>CTD</sub> in the complex, revealing two major species of mass 197.5 kDa and 219.45 kDa (Figure S8B), in contrast to a mass of 132 kDa for the ACAD9 homodimer (Figure S8A). These correspond to an ACAD9 dimer bound to 3 or 4 ECSIT<sub>CTD</sub> monomers, respectively, suggesting that each ACAD9 monomer can bind either a monomer or dimer of ECSIT<sub>CTD</sub>.
ECSIT recognises the vestigial dehydrogenase domain of ACAD9

ACAD9 comprises an N-terminal dehydrogenase domain and a C-terminal region, which, based on homology with VLCAD, includes: (i) a solvent exposed linker (residues 445–482) showing low sequence conservation with VLCAD; (ii) a vestigial domain (residues 493–587) that appears to have arisen by duplication of the N-terminal domain but which has lost its catalytic activity;[14,33] (iii) a C-terminal helix that stabilizes the homodimer (residues 588–621) (Figure S9A). Previous studies postulated that the solvent exposed linker was responsible for the ability of ACAD9, but not VLCAD, to participate in Cl assembly,[14,34] raising the possibility that this region might interact with ECSIT. Interestingly however, the densities tentatively attributed to ECSIT in our cryo-EM map protrude from a different region of ACAD9 (Figure 2H) formed by two structural elements within the vestigial dehydrogenase domain: a helix-turn-helix (residues 554–560) and a loop (residues 488–496)[14] (Figure S9, regions 1 and 2 respectively). Interestingly, both regions are highly conserved across ACAD9 orthologues and, independently, across VLCAD orthologues but are highly divergent between these two proteins (Figure S9B).

In order to test whether the helical stretch of ACAD9 (residues 445–482) located nearby the vestigial domain in the homology model (Figure S9A, highlighted in grey) is also important for binding ECSIT,[14] we designed and purified a chimeric protein, hereafter named ACAD9VLCAD, by replacing this stretch by the equivalent region of VLCAD (Figure S10A). SEC-SAXS analysis showed that the global conformation of ACAD9VLCAD is similar to ACAD9 (Table S1). However, the chimera is still able to co-elute with ECSITVLCAD (Figure S10C), in contrast to VLCAD (Figure S11C), confirming that the identity of the residues within this region is not required for the interaction with ECSIT (Figure S9A).

ECSIT induces the deflavination of ACAD9

To verify whether ECSITVLCAD affects the enzymatic activity of ACAD9, we analysed the acyl-CoA dehydrogenase activity of ACAD9 alone and in complex with ECSITVLCAD. While purified homodimeric ACAD9 bound the FAD cofactor as expected[35] (Figure S12), its acyl-CoA dehydrogenase activity was heavily impaired when bound to ECSITVLCAD (Figure 3A). In contrast, the acyl-CoA activity of VLCAD was not significantly altered in the presence of ECSITVLCAD further confirming that ECSIT specifically interacts with ACAD9 (Figure S11A, B). Intriguingly, chimeric ACAD9VLCAD showed a perturbed FAD oxidation state that correlates with a reduced enzymatic activity (Figure S10A, B), suggesting that one or more specific residues within the helical region are important for catalytic efficiency.

We then investigated the redox state of the FAD cofactor bound to the catalytic pocket of ACAD9, which typically shows a strong yellow colour when oxidized (Figure 3B). Strikingly, the yellow colour was not observed during co-purification of ACAD9 with ECSITVLCAD (Figure 3B). Subsequent quantification of FAD content by UV spectroscopy and liquid chromatography/electrospray ionization (LC/ESI) MS measurements revealed the complete absence of FAD in ACAD9-ECSITVLCAD (Figure 3C). In addition, complex reconstitution by co-incubating the purified proteins showed that FAD is actively released when ECSITVLCAD is added to ACAD9 (Figure 3D). Furthermore, ECSITVLCAD prevents the reuptake of FAD by ACAD9 (Figure 3A), indicating that ECSIT binding inhibits the refлавination of ACAD9. Finally, to obtain structural evidence for the unoccupied state of the FAD binding site, we refined the ACAD9-ECSITVLCAD cryo-EM reconstruction using a tight mask around the compact ACAD9 dimeric core to mitigate the contribution from the disordered ECSITVLCAD (Figure S7). The resulting cryo-EM map at 7.8 Å resolution displayed clear secondary structural features consistent with the VLCAD-based homology model, thus validating this procedure (Figure 3E). Moreover, the resulting map revealed that the FAD binding site is clearly empty in the ECSIT-bound state (Figure 3F), in contrast to other cryo-EM reconstructions of flavoproteins at similar resolution[16,37] and to the crystal structure of FAD-bound VLCAD (PDB ID:3B96)[34] filtered to the resolution of our cryo-EM map (Figure S13), corroborating the role of ECSIT in promoting ACAD9 deflavination and thereby, its loss of enzymatic activity.

Discussion

The mitochondrial Complex I assembly complex (MCIA) is required for the biogenesis of Complex I and is therefore crucial for the activation of the OXPHOS system.[11] FAO and OXPHOS are key pathways involved in cellular energetics.[11] Despite their functional relationship, evidence for a physical interaction between the two pathways is sparse.[14] Understanding how FAO and OXPHOS proteins interact and how defects in these two metabolic pathways contribute to mitochondrial disease pathogenesis is thus of potential importance for the development of new tailored therapeutic strategies. Here, we provide evidence that ECSIT, a protein involved in cytoplasmic and nuclear signalling pathways, acts as the central organising component of the MCIA complex (Figure 4). The modular nature of ECSIT, which is organised into N- and C-terminal binding domains, enables recruitment of its MCIA partners NDUFaf1 and ACAD9 using independent interaction interfaces. We show that the C-terminal region of ECSIT is largely disordered but forms a stable dimer and binds ACAD9 in the region of the latter’s vestigial dehydrogenase domain. Strikingly, interaction with ECSIT induces ACAD9 to eject its FAD cofactor from the catalytic site. Our cryo-EM analysis shows that ECSIT binds far from the ACAD9 FAD binding site. Therefore, the deflavination of ACAD9 presumably occurs via an allosteric mechanism, triggering the shutdown of dehydrogenase activity. Furthermore, this interaction prevents ACAD9 from reassociating with FAD and resuming its catalytic activity. Thus, upon binding to ACAD9, ECSIT actively antagonizes the FAO pathway and redirects ACAD9 to function as a Cl assembly factor. A similar phenomenon recently reported for ETF...
Figure 3. ECSIT induces the deflavination of ACAD9. A) Acyl-CoA dehydrogenase (ACAD) activity of ACAD9 (in green) and the ACAD9-ECSIT<sub>CTD</sub> complex either in absence (red) or in presence (blue) of externally supplied FAD as determined by an ETF fluorescence reduction assay. After addition of the ACAD specific substrate palmitoyl-CoA (C16:0), there is a clear loss of ETF fluorescence in ACAD9 alone but not in complex with ECSIT<sub>CTD</sub>, over 120 s of reaction measurement. The addition of an excess of FAD to the reaction mixture containing the ACAD9-ECSIT<sub>CTD</sub> complex fails to rescue catalytic activity. B) UV visible spectra (FAD absorption region only) of free FAD (black), ACAD9 (magenta) and ACAD9-ECSIT<sub>CTD</sub> (blue dotted line) in the FAD absorption region. Inset: the coloured appearance of the different samples. C) ESI MS spectra recorded in the 780–790 m/z region showing free FAD standard as control (in black, observed m/z 786.17 Da), FAD released from ACAD9 (in magenta, observed m/z 786.16 Da) and absence of FAD signal in the ACAD9-ECSIT<sub>CTD</sub> complex (in blue). D) Release of FAD from the ACAD9 catalytic pocket upon reconstitution of the ACAD9-ECSIT<sub>CTD</sub> complex. Chromatographic elution profiles of the ACAD9-ECSIT<sub>CTD</sub> complex reconstituted upon mixing ACAD9 and ECSIT<sub>CTD</sub>. A UV<sub>280nm</sub> peak at 21 mL (blue line, arrow) is visible, in contrast to the chromatography profile of the co-purified complex with a single elution peak (green). The higher absorbance at UV<sub>260nm</sub> (red line) suggests that it corresponds to the FAD released from the reconstituted complex. Inset: UV visible spectra of the peak contents confirming the presence of FAD. E) Slices through the top (left) and side (right) views of the cryo-EM reconstruction of the ACAD9-ECSIT<sub>CTD</sub> complex core. Consistent with its 7.8 Å resolution, the cryo-EM map shows clear features corresponding to α-helices. The VLCAD-based homology model of ACAD9 is fitted into the cryo-EM map as a rigid body, which explains slight discrepancies between the map and the model, while highlighting their overall good agreement that reflects structural conservation between VLCAD and ACAD9. The dehydrogenase domains and the C-terminal linker and vestigial domains are shown in blue and gold, respectively. F) The cryo-EM map is shown in the same orientations as in (E) but as an isosurface to better illustrate the lack of bound FAD (binding sites in the VLCAD-based homology model are indicated in red). Scale bar = 50 Å. A close-up view is shown in Figure S13.
dehydrogenase holoenzyme, whereby the binding of the ETF regulatory protein LYRM5 induces the efficient removal of FAD, suggests that this negative regulatory mechanism may apply to diverse electron transfer flavoproteins.

That our structural and biophysical analysis reveals that ECSIT stabilizes the ACAD9 homodimer through the vestigial dehydrogenase domain in the absence of FAD, suggests that this domain was co-opted for protein interaction and may have evolved as a module for OXPHOS-related functionality. In contrast, the solvent exposed region previously thought to mediate ACAD9-ECSIT interactions is likely implicated in the catalytic function. Interestingly, however, this region connects the catalytic domain that binds FAD with the vestigial domain that binds ECSIT and might therefore participate in transmitting the allosteric signal from one binding site to the other or, as previously proposed, facilitate the association of ACAD9 with other MCIA membrane associated factors in the inner mitochondrial membrane.

We previously showed that ECSIT interacts with enzymes producing Aβ (e.g. presenilin 2 and apolipoprotein E) and might be involved in AD pathogenesis. Recent studies have shown decreased levels of ECSIT in AD patient brains, with increased ROS and defective mitochondria. Our results suggest that a potential sequestering of ECSIT by Aβ enzymes would thus compromise both the assembly of CI and also the regulation of FAO, a reprogramming of pathways that could lead to altered metabolism in brain mitochondria and ultimately to neurodegeneration.

**Conclusion**

The work presented here reveals a unique role for ECSIT as an assembly and regulatory component of the MCIA complex. Here, ECSIT would direct the core MCIA complex to the inner mitochondrial membrane via ACAD9 to allow the formation of the MCIA holocomplex and would subsequently stabilize a CI intermediate module by its interaction with NDUFAF1 (Figure 4). Furthermore, we suggest that the ECSIT-mediated regulation of the dual functions of ACAD9.
ACAD9 permits crosstalk between the FAO and OXPHOS pathways that contributes to the coordination of the pathways to ensure efficient energy production. On the one hand, the formation of the MCIA complex facilitates the assembly of membrane intermediates as part of CI biogenesis, while on the other, the release of FAD makes ACAD9 quiescent in the initiation of the β-oxidation of fatty acids (Figure 4). More generally, this work enhances our understanding of the control and regulation mechanisms responsible for mitochondrial energy metabolism and should foster future studies into the pathogenesis of diseases entailing OXPHOS and FAO deficiencies. Considering that dimeric ACAD9 is unstable without FAD (Figure S1)[27], and a multifunctional FAO complex is intimately associated with OXPHOS supercomplexes or respirasomes,[28–32] deflavination might be an efficient metabolic switch at the crossroads of assembly and activation of these superstructures.[33] More generally, our work suggests that ECT2 may play the role of a molecular link in bioenergetics and therefore a potential biomarker for mitochondria-targeted diagnostics, particularly for diseases entailing OXPHOS and FAO deficiencies like AD.
