The relationship between Term Graph Rewriting and Term Rewriting is well understood: a single term graph reduction may correspond to several term reductions, due to sharing. It is also known that if term graphs are allowed to contain cycles, then one term graph reduction may correspond to infinitely many term reductions. We stress that this fact can be interpreted in two ways. According to the sequential interpretation, a term graph reduction corresponds to an infinite sequence of term reductions, as formalized by Kennaway et. al. using strongly converging derivations over the complete metric space of infinite terms. Instead according to the parallel interpretation a term graph reduction corresponds to the parallel reduction of an infinite set of redexes in a rational term. We formalize the latter notion by exploiting the complete partial order of infinite and possibly partial terms, and we stress that this interpretation allows to explain the result of reducing circular redexes in several approaches to term graph rewriting.

1 Introduction

The theory of Term Graph Rewriting (TGR) studies the issue of representing finite terms with directed, acyclic graphs, and of modeling term rewriting via graph rewriting. This field has a long history in the realm of theoretical computer science, its origin dating back to the seventies of the last century, when dags were proposed in [25] as an efficient implementation of recursive program schemes. Among the many contributions to the foundations of this field, we mention [26, 5, 22, 20, 10, 1, 8]. The various approaches may differ for the way term graphs are represented or for the precise definition of the graph rewriting mechanism, but they all present equivalent results for what concerns the speed-up of term rewriting due to the explicit sharing.

In fact, the main advantage of using graphs is that when applying a rewrite rule, the subterm matched by a variable $x$ of the left-hand side does not need to be copied if $x$ appears more than once in the right-hand side, because the sharing of subterms can be represented explicitly. Therefore the rewriting process is speeded up, because the rewriting steps do not have to be repeated for each copy of a subterm.

For example, suppose that rule \( s(x) \rightarrow k(x, r(x)) \) is applied to term \( s(f(a)) \), obtaining term \( t = k(f(a), r(f(a))) \). Now rule \( R_f : f(x) \rightarrow g(x) \) can be applied twice to term \( t \), yielding in two steps term \( t' = k(g(a), r(g(a))) \). If instead \( t \) is represented as a graph where the two identical subterms are shared

![Figure 1: An example of term graph rewriting](image-url)
(as in graph $G$ of Figure 1), then a single application of the rule is sufficient to reduce it to graph $G'$ of Figure 1 which clearly represents term $t'$. Thus a single graph reduction may correspond to $n$ term reductions, where $n$ is the “degree of sharing” of the reduced subterm.

Often this fact is spelled out by observing that a single TGR reduction corresponds to a sequence of $n$ term reductions [5, 20], but one may equivalently think that the $n$ term reductions are performed in parallel, in a single step. The idea of reducing families of redexes in parallel (family reductions) was proposed already in [28, 6] as an alternative to the use of dags for representing the sharing of subterms.

Some authors considered the extension of term graph rewriting to the cyclic case, allowing (finite, directed) cyclic graphs as well. Actually, already in [5] the definition did not forbid cycles, and the relationship with term rewriting in this case was analyzed in depth in [23], as discussed below. It was observed that allowing term graphs with cycles one could represent certain structures that arise when dealing with recursive definitions (as for the implementation of the fixed point operator $Y$ proposed in [27]). Interestingly, even using acyclic rules, cyclic graphs can be produced by rewriting in presence of suitable sharing strategies [17, 18]. Cyclic term graph rewriting was also defined abstractly in a categorical setting in [9], showing the equivalence with an operational definition; and it was discussed in the framework of Equational Term Graph Rewriting in [1].

A renewed interest in term graph rewriting with cycles is witnessed by some recent publications. In [3, 4] the authors propose an extension of the p-calculus where the sharing of subterms can be modeled explicitly and cyclic definitions are allowed. In [15] cyclic term graphs are used to represent data structures, and rewriting models the transformation of such structures with both local and global redirection of pointers. In [14] they are used for the definition of the type system of an object oriented language.

Considering the relationship with term rewriting, the first consequence of the extension to cyclic term graphs is that infinite terms (or, more precisely, rational terms, i.e., infinite terms with a finite number of distinct subterms) can be represented as well. The second effect is that a single graph reduction may now correspond to some infinite term rewriting. Consider for example rule $R_f$ above: by applying it to graph $H$ of Figure 2 one obtains the graph $H'$. Clearly, $H$ represents the infinite term $f^{\omega} = f(f(f(\ldots)))$, while $H'$ represents term $g^{\omega}$. As for the finite case, there are two possible ways of interpreting the rewriting of term $f^{\omega}$ to term $g^{\omega}$ via infinitely many applications of rule $R_f$:

[**sequential interpretation**] $g^{\omega}$ is the limit of an infinite sequence of applications of $R_f$, i.e., $f^{\omega} \rightarrow_{R_f} g(f^{\omega}) \rightarrow_{R_f} g(g(f^{\omega})) \rightarrow_{R_f} \ldots \rightarrow_{\omega} g^{\omega}$.

[**parallel interpretation**] $g^{\omega}$ is the result of the simultaneous application of $R_f$ to an infinite number of redexes in $f^{\omega}$: in a single step all the occurrences of $f$ in $f^{\omega}$ are replaced by $g$.

The first interpretation has been thoroughly formalized in [12, 13, 17, 18, 23], where the authors elaborated a theory of (rational) transfinite term rewriting, showing that finite, cyclic graph rewriting is an adequate implementation for it. In essence, a finite graph derivation sequence has the “same effect” of a strongly convergent infinite term rewriting sequence. As far as the notion of convergence is concerned, the well-known topological structure of (possibly infinite) terms is used, which, equipped with a suitable notion of distance, form a complete ultra-metric space [2].
In this paper we provide instead a formalization of the parallel interpretation above. To this aim we exploit the theory of infinite parallel term rewriting that has been proposed by the first author in [7] by exploiting the complete partially ordered structure of $CT_{Σ}$, the collection of possibly infinite, possibly partial terms over signature $Σ$.

Interestingly, unlike the acyclic case for which the sequential and the parallel interpretations of term graph rewriting are completely equivalent, in the cyclic case there are cases where the two interpretations lead to different results. This happens when collapsing rules are considered, i.e., rules having a variable as right-hand side. The canonical collapsing rule is the rule for identity, $R_I : I(x) → x$, and the pathological case (considered already by many authors) is the application of $R_I$ to $I^ω$. Using the sequential interpretation, we have that $I^ω →^{R_I} I^ω →^{R_I} I^ω$, and thus the limit of the sequence is $I^ω$ itself. Instead according to the parallel interpretation all the occurrences of $I$ in $I^ω$ are deleted in a single step, and thus we should obtain as result a term that does not contain any function symbol: we will show indeed that we get the completely undefined term $⊥$, the bottom element of the complete partial ordering $CT_{Σ}$.

Both the sequential and the parallel interpretations turn out to be meaningful from the point of view of cyclic term graph rewriting, because depending on the chosen rewriting approach one can get different results when applying the collapsing rule $R_I$ to the circular-$I$, i.e., to the graph having a single node labelled by $I$ and a loop, which clearly unravels to $I^ω$. In fact, if one uses the operational definition of term graph rewriting proposed in [5] (as done in [23, 17, 18]) then the circular-$I$ reduces via $R_I$ to itself, and this is consistent with the sequential interpretation.

Instead for several other definitions of term graph rewriting (including the double-pushout [20], the single-pushout [22], the equational [1], and the categorical [9] approaches) the circular-$I$ rewrites via $R_I$ to a graph consisting of a single, unlabeled node, which can be regarded as the graphical representation of the undefined term $⊥$, and is therefore consistent with the parallel interpretation.

The paper is organized as follows. In Section 2 we summarize the basic definitions about infinite terms [19], orthogonal term rewriting [21], and parallel term rewriting [7]. In Section 3 we introduce (possibly cyclic) term graphs, and we make precise their relationship with (sets of) rational terms, via the unraveling function. Algebraic term graph rewriting is the topic of Section 4 where we recall the basics of the double-pushout approach [16], apply it to the category of term graphs, and provide an encoding of term rewrite rules as graph rules. The main results of the paper are in Section 5. We first prove that a single reduction of a graph induces on the unraveled term a possibly infinite parallel reduction. Next this fact is used as a main lemma in the proof that the unraveling function is an adequate mapping from any orthogonal TGRS system to the orthogonal TRS obtained by unraveling its rules, provided that only rational terms and rational parallel reduction sequences are considered. Finally in Section 6 we summarize our contribution.

2 Infinite terms and parallel term rewriting

In this background section we first introduce the algebra $CT_{Σ}$ of possibly partial, possibly infinite terms. The collection of such terms forms a complete partial ordering which has been studied in depth in [19]. Next we introduce the basic definitions related to (orthogonal) term rewriting, which apply to infinite terms as well. Finally, we introduce the definition of infinite parallel rewriting, which exploits the CPO structure of terms according to [7].
2.1 Infinite Terms

Most of the following definitions are borrowed from [19].

Let \( \omega^* \) be the set of all finite strings of positive natural numbers. Elements of \( \omega^* \) are called occurrences. The empty string is denoted by \( \lambda \), and \( u \leq w \) indicates that \( u \) is a prefix of \( w \). Occurrences \( u, w \) are called disjoint (written \( u \not\leq w \) if neither \( u \leq w \) nor \( w \leq u \).

Let \( \Sigma \) be a (one-sorted) signature, i.e., a ranked alphabet of operator symbols \( \Sigma = \bigcup_{n \in \mathbb{N}} \Sigma_n \) and let \( X \) be a set of variables. A term over \( \Sigma \times X \) is a partial function \( t : \omega^* \to \Sigma \cup X \), such that the domain of definition of \( t \), \( \mathcal{O}(t) \), satisfies the following (where \( w \in \omega^* \) and all \( i \in \omega \)):

- \( \forall i \in \mathcal{O}(t) \Rightarrow w \in \mathcal{O}(t) \)
- \( \forall i \in \mathcal{O}(t) \Rightarrow \forall (w \in \omega^*) \exists j \geq i \cdot t_j(w) = t(u) \).

\( \mathcal{O}(t) \) is called the set of occurrences of \( t \). We denote by \( \bot \) (called bottom) the empty term, i.e. the only term such that \( \mathcal{O}(\bot) = \emptyset \).

Given an occurrence \( w \in \omega^* \) and a term \( t \), the subterm of \( t \) at (occurrence) \( w \) is the term \( t/w \) defined as \( t/w(u) = t(wu) \) for all \( u \in \omega^* \). A term \( t \) is finite if \( \mathcal{O}(t) \) is finite; it is total if \( \mathcal{O}(t) = \omega^* \); it is linear if no variable occurs more than once in \( t \); and it is rational if it has a finite number of different subterms. Given terms \( t, s \) and an occurrence \( w \in \omega^* \), the replacement of \( s \) in \( t \) at (occurrence) \( w \), denoted \( t[w \leftarrow s] \), is the term defined as \( t[w \leftarrow s](u) = t(u) \) if \( w \not\leq u \) or \( t/w = \bot \), and \( t[w \leftarrow s](wu) = s(u) \) otherwise.

The set of terms over \( \Sigma \) is denoted by \( CT_\Sigma(X) \) (\( CT_\Sigma \) stays for \( CT_\Sigma(\emptyset) \)). Throughout the paper we will often use (for finite terms) the equivalent and more usual representation of terms as operators applied to other terms. Partial terms are made total in this representation by exploiting the empty term \( \bot \). Thus, for example, if \( x \in X \), \( t = f(\bot, g(x)) \) is the term such that \( \mathcal{O}(t) = \{ \lambda, 2 \cdot 2 \cdot 1 \} \), \( \lambda(x) = f(x, g(x)) \), and \( t(2) = g \in \Sigma_1 \), and \( t(2 \cdot 1) = x \in X \).

It is well known that \( CT_\Sigma(X) \) forms a complete partial order with respect to the “approximation” relation. We say that \( t \) approximates \( t' \) (written \( t \leq t' \)) iff \( t \) is less defined than \( t' \) as partial function. The least element of \( CT_\Sigma(X) \) with respect to \( \leq \) is clearly \( \bot \). An \( \omega \)-chain \( \{ t_i \}_{i \in \omega} \) is an infinite sequence of terms \( t_0 \leq t_1 \leq \ldots \).

Every \( \omega \)-chain \( \{ t_i \}_{i \in \omega} \) in \( CT_\Sigma(X) \) has a least upper bound (lub) \( \bigcup_{i \in \omega} t_i \) characterized as follows:

\[
\forall \exists w \in \omega^* \exists i < \omega \forall j \geq i \cdot t_j(w) = t(w)
\]

Moreover, every pair of terms has a greatest lower bound. All this amounts to say that \( CT_\Sigma(X) \) is an \( \omega \)-complete lower semilattice.

2.2 Term Rewriting

We recall here the basic definitions of (orthogonal) term rewriting [21], which apply to infinite terms as well.

Let \( X \) and \( Y \) be two sets of variables. A substitution (from \( X \) to \( Y \)) is a function \( \sigma : X \to CT_\Sigma(Y) \) (used in postfix notation). Such a substitution \( \sigma \) can be extended in a unique way to a continuous (i.e., monotonic and lub-preserving) function \( \sigma : CT_\Sigma(X) \to CT_\Sigma(Y) \), which extends \( \sigma \) as follows:

- \( \bot \sigma = \bot \)
- \( f(t_1, \ldots, t_n) \sigma = f(t_1 \sigma, \ldots, t_n \sigma) \)
- \( (\bigcup_{i \in \omega} t_i) \sigma = \bigcup_{i \in \omega} t_i \sigma \)
A rewrite rule $R = (l, r)$ is a pair of total terms of $CT_\Sigma(X)$, where $\text{var}(r) \subseteq \text{var}(l)$, $l$ is finite and it is not a variable. Terms $l$ and $r$ are called the left- and the right-hand side of $R$, respectively. A rule is called left-linear if $l$ is linear, and it is collapsing if $r$ is a variable. A term rewriting system (shortly TRS) $\mathcal{R}$ is a finite set of rewrite rules, $\mathcal{R} = \{R_i\}_{i \in I}$.

Given a term rewriting system $\mathcal{R}$, a redex (for REDucible EXpression) $\Delta$ of a term $t$ is a pair $\Delta = (w, R)$ where $R : l \rightarrow r \in \mathcal{R}$ is a rule, and $w$ is an occurrence of $t$, such that there exists a substitution $\sigma$ which realizes $\Delta$, i.e., such that $t/w = l\sigma$. In this case we say that $t$ reduces (via $\Delta$) to the term $t' = t[w \leftarrow r\sigma]$, and we write $t \rightarrow_\Delta t'$ or simply $t \rightarrow t'$. A reduction sequence $t_1 \rightarrow t_2 \rightarrow \ldots t_n$ is a finite sequence of reductions.

A TRS $\mathcal{R}$ is orthogonal (shortly, it is an OTRS) if all the rules in $\mathcal{R}$ are left-linear and it is non-overlapping: that is, the left-hand side of each rule does not unify with a non-variable subterm of any other rule in $\mathcal{R}$, or with a proper, non-variable subterm of itself. In this paper we will be concerned with orthogonal TRS's only, because the confluence of such systems is a key property needed in the next section to define parallel term rewriting.

2.3 Parallel Term Rewriting

As discussed in the introduction, in the parallel interpretation of term graph rewriting the reduction of a cyclic graph corresponds to the parallel reduction of a possibly infinite set of redexes in the corresponding term. The definitions below summarize, in a simplified way, those in [7]. Intuitively, finite parallel rewriting can be defined easily by exploiting the confluence of orthogonal term rewriting. In fact, the parallel reduction of a finite number of redexes is defined simply as any complete development of them: Any such development ends with the same term, so the result is well defined. Let us recall the relevant definitions.

Given two redexes of a term, the reduction of one of them can transform the other in various ways. The second redex can be destroyed, it can be left intact, or it can be copied a number of times. This is captured by the definition of residuals. We assume here that the rules belong to an OTRS, thus two redexes in a term are either the same or do not overlap.

Definition 1 (residuals). Let $\Delta = (w, R)$ and $\Delta' = (w', R' : l' \rightarrow r')$ be two redexes in a term $t$. The set of residual of $\Delta$ by $\Delta'$ is denoted by $\Delta \setminus \Delta'$, and it is defined as

$$\Delta \setminus \Delta' = \begin{cases} \emptyset & \text{if } \Delta = \Delta' \\ \{\Delta\} & \text{if } w \not\equiv w' \\ \{(w'w_{x}u, R) \mid r'/w_{x} = l'/v_{x}\} & \text{if } w = w'v_{x}u \text{ and } l'/v_{x} \text{ is a variable} \end{cases}$$

If $\Phi$ is a finite set of redexes of $t$ and $\Delta$ is a redex of $t$, then the set of residuals of $\Phi$ by $\Delta$, denoted $\Phi \setminus \Delta$, is defined as the union of $\Delta \setminus \Delta'$ for all $\Delta' \in \Phi$.

If $\Phi$ is a set of redexes of $t$ and $s = (t \rightarrow_{\Delta_1} t_1 \ldots \rightarrow_{\Delta_n} t_n)$ is a reduction sequence, then $\Phi \setminus s$ is defined as $\Phi$ if $n = 0$, and as $(\Phi \setminus \Delta_1) \setminus s'$, where $s' = (t_1 \rightarrow_{\Delta_2} t_2 \ldots \rightarrow_{\Delta_n} t_n)$, otherwise.

In the last definition, if $t \rightarrow_{\Delta} t'$ and $\Delta'$ is a redex of $t$, the orthogonality of the system ensures that every member of $\Delta' \setminus \Delta$ is a redex of $t'$.

Definition 2 (complete development). Let $\Phi$ be a finite set of redexes of $t$. A development of $\Phi$ is a reduction sequence such that after each initial segment $s$, the next reduced redex is an element of $\Phi \setminus s$. A complete development of $\Phi$ is a development $s$ such that $\Phi \setminus s = \emptyset$.

---

1The restriction to left-finite rules can be motivated intuitively, as in [23], by the requirement of checking in finite time the applicability of a rule to a term. On a more technical ground, in [7] it is shown that point 3 of Theorem 6 below does not hold for left-infinite rules.
The following well-known fact \cite{Klop} is a consequence of the parallel moves lemma \cite{Plotkin}.

**Proposition 3.** All complete developments \(s\) and \(s'\) of a finite set of redexes \(\Phi\) in a term \(t\) are finite, and end with the same term. Moreover, for each redex \(\Delta\) of \(t\), it holds \(\Delta \setminus s = \Delta \setminus s'\). Therefore we can safely denote by \(\Delta \setminus \Phi\) the residuals of \(\Delta\) by any complete development of \(\Phi\) (and similarly replacing \(\Delta\) with a set of redexes \(\Phi'\) of \(t\)).

Exploiting this fact, we define the parallel reduction of a finite set of redexes as any complete development of them.

**Definition 4 (finite parallel redex reduction).** A **parallel redex** \(\Phi\) of a term \(t\) is a (possibly infinite, necessarily countable) set of distinct redexes in \(t\). Given a finite parallel redex \(\Phi\) of \(t\), we write \(t \rightarrow_\Phi t'\) and say that there is a (finite) **parallel reduction** from \(t\) to \(t'\) if there exists a complete development \(t \rightarrow_{\Delta_1} t_1 \rightarrow_{\Delta_2} t_2 \rightarrow_\Phi t'\) of \(t\).

We are now ready to extend the definition of application of parallel redexes to the infinite case. Given an infinite parallel redex \(\Phi\) (i.e., an infinite set of redexes) of a term \(t\), we consider a chain of approximations of \(t\), \(t_0 \leq t_1 \leq t_2 \ldots\), such that their limit is \(t\), and that only a finite subset of \(\Phi\) applies to each \(t_i\). For each \(i < \omega\), let \(\Phi_i\) be the finite subset of \(\Phi\) containing all and only those redexes of \(t\) which are also redexes of \(t_i\), and call \(d_i\) the result of the parallel reduction of \(\Phi_i\), i.e., \(t_i \rightarrow_\Phi d_i\). Then the crucial fact is that the sequence of terms \(d_0, d_1, d_2, \ldots\) defined in this way forms a chain: by definition we say that there is an infinite parallel reduction from \(t\) to \(d = \bigcup_{i < \omega} d_i\) via \(\Phi\), written \(t \rightarrow_\Phi d\). Here is the formal definition.

**Definition 5 (parallel redex reduction).** Given an infinite parallel redex \(\Phi\) of a term \(t\), let \(t_0 \leq t_1 \leq \ldots t_n \leq \ldots\) be any chain approximating \(t\) (i.e., such that \(\bigcup_{i < \omega} \{t_i\} = t\)) and such that:

- For each \(i < \omega\), every redex \((w, R) \in \Phi\) is either a redex of \(t_i\) or \(t_i(w) = \perp\). That is, the image of the lhs of every redex in \(\Phi\) is either all in \(t_i\), or it is outside, but does not “cross the boundary”.

- For each \(i < \omega\), let \(\Phi_i \subseteq \Phi\) be the subset of all redexes in \(\Phi\) which are also redexes of \(t_i\); then \(\Phi_i\) must be finite.

For each \(i < \omega\), let \(d_i\) be the result of the (finite) parallel reduction of \(t_i\) via \(\Phi_i\) (i.e., \(t_i \rightarrow_\Phi d_i\)). Then we say that there is an (infinite) **parallel reduction** from \(t\) to \(d \stackrel{\text{def}}{=} \bigcup_{i < \omega} d_i\) via \(\Phi\), and we write \(t \rightarrow_\Phi d\).

Note that in the last definition if the chain approximating \(t\) contains finite terms only, then the second condition is automatically satisfied. We consider more general chains, possibly including infinite terms, because they arise naturally in the proof of Theorem \cite{Plotkin}. The main result of this section states that the last definition is well-given. For a proof we refer to \cite{Klop} (Theorem 32).

**Theorem 6 (parallel redex reduction is well-defined).** Definition 5 is well given, that is:

1. **given an infinite parallel redex \(\Phi\) of a term \(t\), there exists a chain \(t_0 \leq t_1 \leq \ldots t_n \leq \ldots\) approximating \(t\) and satisfying the conditions of Definition 5.**

2. **in this case, \(\forall 0 \leq i < j < \omega. d_i \leq d_j\), thus \(\{d_i\}_{i < \omega}\) is a chain;**

3. **the result of the infinite parallel reduction of \(t\) via \(\Phi\) does not depend on the choice of the chain approximating \(t\), provided that it satisfies the required conditions.**

As an example, let us consider again the two infinite reductions mentioned in the introduction, according to the parallel interpretation. In the term reduction from \(f^\omega\) to \(g^\omega\) (corresponding to the graph reduction of Figure \cite{Plotkin}), there are infinitely many redexes of rule \(R_f\) in the term \(f^\omega\), namely at occurrences
\(\lambda, 1, 1 \cdot 1, \ldots\). Let \(\Phi = \{\Delta_n = (1^n, R_f) \mid n \in \mathbb{N}\}\) be this infinite parallel redex of \(f^0\). As for the chain of terms approximating \(t = f^0\), let us choose \(t_0 = \bot, t_1 = f(\bot), \ldots, t_n = f^n(\bot)\). Clearly, for each \(n\) the set \(\Phi_n \subseteq \Phi\) of redexes of \(t_n\) contains exactly \(n\) redexes. For each \(n\) we have \(t_n = f^n(\bot) \rightarrow_{\Phi_n} g^n(\bot)\), and thus, according to the definition, the result of the parallel reduction of \(f^0\) via \(\Phi\) is \(\bigcup_{i < \omega} \{g^i(\bot)\} \equiv g^0\).

In the case of rule \(R_1\) and of the circular \(I\), choosing a similar approximating chain we have \(\Phi = \{\Delta_n = (1^n, R_1) \mid n \in \mathbb{N}\}\), \(t_n = I^n(\bot)\) for each \(n\), \(t_n = I^n(\bot) \rightarrow_{\Phi_n} \bot\), and thus \(I^0\) reduces by \(\Phi\) to \(\bigcup_{i < \omega} \{\bot\} = \bot\).

We shall need the following easy result.

**Proposition 7** (strong confluence of parallel reduction). Given an orthogonal TRS \(\mathcal{R}\), parallel reduction is strong confluent, i.e., if \(t' \xrightarrow{\mathcal{R}} t \rightarrow_{\Phi} t''\), then there exist \(t''', \Psi, \Psi'\) such that \(t' \rightarrow_{\Psi} t''' \rightarrow_{\Psi'} t''\). As a consequence, parallel reduction is confluent.

### 3 Term Graphs and Rational Terms

We summarize here the definition of term graphs (or simply graphs), and their relationship with rational terms, as introduced in [23]. However, since we will apply to those graphs the algebraic approach to graph rewriting, we shall slightly adapt the definition to our framework, emphasizing the categorical structure of the collection of graphs.

Term graphs are obtained from the usual representation of terms with sharing as dag’s (directed acyclic graph), by dropping the acyclicity requirement. In such a way, a finite cyclic graph may represent a possibly infinite, but rational term.

**Definition 8** (term graphs). Let \(\Sigma\) be a fixed, one-sorted\(^2\) signature. A (term) graph \(G\) (over \(\Sigma\)) is a triple \(G = (N_G, s_G, l_G)\), where

- \(N_G\) is a finite set of nodes,
- \(s_G : N_G \rightarrow N_G\) is a partial function, called the successor function,
- \(l_G : N_G \rightarrow \Sigma\) is a partial function, called the labelling function.

Moreover, it is required that \(s_G\) and \(l_G\) are defined on the same subset of \(N_G\), and that for each node \(n \in N_G\), if \(l_G(n)\) is defined and it is an operator of arity \(k\), then \(s_G(n)\) has length exactly \(k\).

**Definition 9** (morphisms, category of term graphs). A (graph) morphism \(f : G \rightarrow H\) between two graphs \(G\) and \(H\) is a function \(f : N_G \rightarrow N_H\), which preserves labelling and successor functions, i.e., for each \(n \in N_G\), if \(l_G(n)\) is defined, then \(l_H(f(n)) = l_G(n)\) and \(s_H(f(n)) = f^*(s_G(n))\) (where \(f^*\) is the obvious extension of \(f\) to lists of nodes).

The composition of graph morphisms is defined in the obvious way, and it is clearly associative; moreover, the identity function on nodes is a morphism, and therefore term graphs (over \(\Sigma\)) and their morphisms form a category that will be denoted by \(\text{TGraph}_\Sigma\).

Thanks to the conditions imposed on term graphs in Definition\(^8\) a term of \(CT\Sigma\) can be extracted or unraveled from every node of a graph.

**Definition 10** (from term graphs to terms and backwards). A path \(\pi\) in a graph \(G = (N_G, s_G, l_G)\) from node \(n\) to node \(n'\) is a finite sequence \(\pi = \langle n_1, j_1, n_2, j_2, \ldots, j_k, n_{k+1}\rangle\), where all \(j_i\) are natural numbers,\(^3\) the generalization to many-sorted signatures is straightforward, by labeling nodes with pairs \((\text{operator}, \text{sort})\), with the obvious meaning.
all \( n_i \) are nodes, and such that \( n_1 = n, n_{k+1} = n' \), and for all \( 1 \leq i \leq k, s_G(n_i)|_{j_i} = n_{i+1} \) (here \( s_i \) denotes the \( i \)-th element of the sequence \( s \)). It follows that there exists exactly one empty path \( 'n' \) from each node \( n \) to itself. The occurrence of a path \( \pi = \langle n_1, j_1, n_2, j_2, \ldots, j_k, n_{k+1} \rangle \) is the list of natural numbers \( j_1 \cdot j_2 \cdots j_k \) and it is denoted by \( \mathcal{O}(\pi) \). Thus \( \mathcal{O}(\pi) = \lambda \) if \( \pi \) is an empty path. Clearly, for each node \( n \) there is at most one path in \( G \) having a given occurrence \( w \).

A graph \( G \) is acyclic if there are no non-empty paths from one node to itself; graph \( G \) is a tree with root \( \overline{n} \in N_G \) iff there exists exactly one path from \( \overline{n} \) to any other node of \( G \).

Let \( G = (N_G, s_G, l_G) \) be a term graph. The set \( var(G) \subseteq N_G \) of variable nodes or empty nodes of \( G \) is the set of nodes on which the labeling function (and thus also the successor function) is undefined. For each node \( n \in N_G \), \( U[G,n] \), the unraveling of \( G \) at \( n \) is the term defined as

\[
U[G,n](w) = \begin{cases} 
  n' & \text{if there is a path } \pi \text{ from } n \text{ to } n' \text{ with } \mathcal{O}(\pi) = w \text{ and } n' \in var(G) \\
  l_G(n') & \text{if there is a path } \pi \text{ from } n \text{ to } n' \text{ with } \mathcal{O}(\pi) = w \text{ and } n' \not\in var(G) 
  \end{cases}
\]

for all \( w \in \omega^* \). It follows immediately from these definitions that for each \( n \in N_G \) and for each occurrence \( w \), \( U[G,n](w) = U[G,n'] \) iff there exists a path \( \pi \) from \( n \) to \( n' \) with \( \mathcal{O}(\pi) = w \). By \( \mathcal{U}[G] \) we denote the set \( \mathcal{U}[G] = \{ U[G,n] | n \in N_G \} \).

Conversely, let \( T \) be a finite set of rational terms, and let us denote by \( \overline{T} \) its closure under the subterm relation (i.e., \( \overline{T} = \{ t | t \text{ is a subterm of some term in } T \} \) ). Then the term graph representation of \( T \), denoted \( \mathcal{T}[T] \), is the graph \( \mathcal{T}[T] = (N_{\mathcal{T}[T]}, s_{\mathcal{T}[T]}, l_{\mathcal{T}[T]}) \) defined as follows:

1. \( N_{\mathcal{T}[T]} = \overline{T} \);
2. \( s_{\mathcal{T}[T]}(t) = \langle t_1, \ldots, t_k \rangle \) if \( t = f(t_1, \ldots, t_k) \), and undefined if \( t \) is a variable;
3. \( l_{\mathcal{T}[T]}(t) = f \) if \( t = f(t_1, \ldots, t_k) \), and undefined if \( t \) is a variable.

It is quite easily seen that, for every term graph \( G \) and node \( n \in N_G \), \( \mathcal{U}[G,n] \) is a well-defined and total term containing variables in \( var(G) \) (thus \( \mathcal{U}[G,n] \in CT_{\Sigma}(var(G)) \)). Such term can be infinite (because in a cyclic graph there can be infinitely many paths starting from one node), but since \( G \) is finite by definition, \( \mathcal{U}[G,n] \) is necessarily a rational term, because the number of distinct subterms is bounded by the cardinality of \( N_G \). It is worth noting also that if \( G \) is a tree with root \( \overline{n} \), then \( \mathcal{U}[G,n] \) is a finite and linear term.

The above definitions made clear the relationship between objects of category \( \text{TGraph}_{\Sigma} \) and terms in \( CT_{\Sigma} \). Such relationship can be extended to arrows of \( \text{TGraph}_{\Sigma} \) and to term substitutions as follows.

**Proposition 11** (from morphism to substitutions and backwards). Let \( f : G \to H \) be a term graph morphism. The substitution induced by \( f \) is the substitution \( \sigma_f : var(G) \to CT_{\Sigma}(var(H)) \), defined as \( x\sigma_f = \mathcal{U}[H,f(x)] \) for all \( x \in var(G) \). Moreover the following hold:

1. If \( f : G \to H \) is a morphism, then \( \sigma_f \circ \mathcal{U}[G] = \mathcal{U}[H] \circ f \).
2. Let \( G \) be a tree with root \( \overline{n} \) and let \( \mathcal{U}[G,n] = t \). Then for every graph \( H \) and every node \( n' \in N_H \) with \( t' = \mathcal{U}[H,n'] \), there is a substitution \( \sigma \) such that \( \sigma t = t' \) if and only if there is a morphism \( f : G \to H \) where \( f(\overline{n}) = n' \). Moreover in this case we have \( \sigma = \sigma_f \).

## 4 Algebraic term graph rewriting

We introduce now term graph rewriting according to the algebraic, double-pushout approach [16]. Let \( \text{Graph} \) be a fixed category of graphs (below we will apply the general definitions to the category of
term graphs defined in Section 3. The basic categorical construction in the algebraic definition of graph rewriting is that of pushout.

**Definition 12** (pushout \([24]\) and pushout complement \([16]\)). Given a category \(C\) and two arrows \(b : K \to B\), \(d : K \to D\) of \(C\), a triple \(\langle H, h : B \to H, c : D \to H \rangle\) as in Figure 3(a) is called a **pushout** of \(\langle b, d \rangle\) if [Commutativity] \(h \circ b = c \circ d\), and [Universal Property] for all objects \(H'\) and arrows \(h' : B \to H'\) and \(c' : D \to H'\), with \(h' \circ b = c' \circ d\), there exists a unique arrow \(f : H \to H'\) such that \(f \circ h = h'\) and \(f \circ c = c'\).

In this situation, \(H\) is called a **pushout object** of \(\langle b, d \rangle\). Moreover, given arrows \(b : K \to B\) and \(h : B \to H\), a **pushout complement** of \(\langle b, h \rangle\) is a triple \(\langle D, d : K \to D, c : D \to H \rangle\) such that \(\langle H, h, c \rangle\) is a pushout of \(b\) and \(d\). In this case \(D\) is called a **pushout complement object** of \(\langle b, h \rangle\).

**Definition 13** (graph grammars, direct derivations \([16]\)). A **(graph) production** \(p = (L \xleftarrow{l} K \xrightarrow{r} R)\) is a pair of injective graph morphisms \(l : K \to L\) and \(r : K \to R\). The graphs \(L, K,\) and \(R\) are called the **left-hand side**, the **interface**, and the **right-hand side** of \(p\), respectively. A **graph transformation system** \(\mathcal{G} = \{p_i\}_{i \in I}\) is a set of graph productions.

Given a graph \(G\), a graph production \(p = (L \xleftarrow{l} K \xrightarrow{r} R)\), and an occurrence (i.e., a graph morphism) \(g : L \to G\), a **direct derivation** \(\alpha\) from \(G\) to \(H\) using \(p\) **(based on \(g\))** exists if and only if the diagram in Figure 3(b) can be constructed, where both squares are required to be pushouts in \(\text{Graph}\). In this case, \(D\) is called the **context** graph, and we write \(\alpha : G \Rightarrow_p^g H\), or simply \(\alpha : G \Rightarrow_p H\).

In a graph-theoretical setting, the pushout object \(H\) of Figure 3(a) can be understood as the gluing of graphs \(B\) and \(D\), obtained by identifying the images of \(K\) along \(b\) and \(d\). Therefore the double-pushout construction can be interpreted as follows. In order to apply the production \(p\) to \(G\), we first need to find an occurrence of its left-hand side \(L\) in \(G\), i.e., a graph morphism \(g : L \to G\). Next, to model the deletion of that occurrence from \(G\), we have to find a graph \(D\) and morphisms \(k\) and \(d\) such that the resulting square is a pushout: The context graph \(D\) is characterized categorically as the pushout complement object of \(\langle l, g \rangle\). Finally, we have to embed the right-hand side \(R\) into \(D\): This embedding is expressed by the right pushout.

The conditions for the existence of pushouts and of pushout complements depend on the category \(\text{Graphs}\) for which the above definitions are introduced. Since we are interested just in the graph productions that represent term rewrite rules, in the rest of the paper we shall consider such definitions in the category \(\text{TGraph}_\Sigma\), and we will present conditions for the existence of pushouts and pushout complements (see Proposition 17) only for a specific format of productions, called evaluation rules (according to the name in [20], where the acyclic case is considered). Such evaluation rules are term graph productions satisfying some additional requirements that make them suitable to represent term rules.

**Definition 14** (evaluation rules). An **evaluation rule** is a term graph production \(p = (L \xleftarrow{l} K \xrightarrow{r} R)\) such that
1. $L$ is a tree and it is not a single empty node. Let $\varphi$ be the root of $L$.

2. $K = (N_L, s_L, l_L, (N_L \setminus \{\varphi\}))$, that is, $K$ is obtained from $L$ by making the successor and labeling functions undeﬁned on the root. Morphism $l : K \to L$ is the inclusion; notice that $l$ is an isomorphism on nodes and that $\text{var}(K) = \text{var}(L) \cup \{\varphi\}$.

3. If restricted to $\text{var}(L) \subset \text{var}(K)$, morphism $r : K \to R$ is an isomorphism between $\text{var}(L)$ and $\text{var}(R)$.

Let us make explicit the relationship between evaluation rules and rewrite rules. From every evaluation rule $p$ one can easily unravel a term rewrite rule $\mathcal{U}[p]$; furthermore, for each rewrite rule $R$ we propose a suitable representation as evaluation rule, $\mathcal{G}[R]$.

**Definition 15** (from evaluation to rewrite rules and backwards). Let $p = (L \leftarrow^f K \rightarrow^r R)$ be an evaluation rule. The unraveling of $p$ is the term rewrite rule $\mathcal{U}[p] : t \to s$ deﬁned as follows.

1. $t = \mathcal{U}_L[p]$ (where $\varphi$ is the root of $L$, as usual);
2. $s = \mathcal{U}_R[r(\varphi)]\sigma$, where $\sigma : \text{var}(R) \to \text{var}(L)$ is the substitution deﬁned as $\sigma(x) = y$ if $r(y) = x$.

We shall say that an evaluation rule $p$ is non-self-overlapping if so is the rewrite rule $\mathcal{U}[p]$. A term graph rewriting system (shortly TGRS) $\mathcal{P}$ is a ﬁnite set of evaluation rules, $\mathcal{P} = \{p_i\}_{i \in I}$; $\mathcal{P}$ is called orthogonal if so is the term rewriting system $\mathcal{U}[\mathcal{P}] \deq \{\mathcal{U}[p] \mid p \in \mathcal{P}\}$.

The other way around, let $R : t \to s$ be a rational, left-ﬁnite and left-linear term rewrite rule, and let $t = f(t_1, \ldots , t_k)$ ($t$ must have this form because it cannot be a variable). Then its graph representation $\mathcal{G}[R]$ is the production $\mathcal{G}[R] = (L \leftarrow^f K \rightarrow^r R)$, where

1. $L = \mathcal{G}\{t\}$ (by $T$ we denote the closure of $T$ with respect to the subterm relation).
2. $K$ and $l : K \to L$ are deﬁned according to point 2 of Deﬁnition 14.
3. $R = \mathcal{G}\{s,t_1,\ldots , t_k\}$.
4. $r : K \to R$ is deﬁned as $r(\varphi) = s$, and $r(n) = \mathcal{U}_K[n]$ if $n \in N_K \setminus \{\varphi\}$ (this is well-deﬁned because the nodes of $R$ are subterms of $\{s,t_1,\ldots , t_k\}$, according to Deﬁnition 10).

By the properties of the unraveling function and of evaluation rules (Deﬁnitions 10 and 14) it is routine to check that for each evaluation rule $p$ the term rewrite rule $\mathcal{U}[p]$ is well-deﬁned, rational, total, left-ﬁnite, and left-linear (the last two because the left-hand side of an evaluation rule is a tree). The substitution $\sigma$ applied to $\mathcal{U}_R[r(\varphi)]$ in the above deﬁnition is needed to ensure that $\text{var}(s) \subseteq \text{var}(t)$. Similarly, it follows directly from the deﬁnitions that $\mathcal{G}[R]$ is a well-deﬁned evaluation rule for each term rewrite rule $R$ satisfying the required conditions.

**Example 16** (evaluation rules). Figure 4 shows the evaluation rules $\mathcal{G}[R_f]$ and $\mathcal{G}[R_{cdr}]$, which are the graph representations of the rewrite rules $R_f : f(x) \to g(x)$ and $R_{cdr} : \text{cdr}(\text{cons}(x,y)) \to y$. The left morphisms of the rules are the obvious inclusions, while the right morphisms are determined by the mapping of nodes that is depicted with dotted arrows. Rule $R_{cdr}$ is a collapsing rule which describes the behaviour of the $\text{cdr}$ operator on LISP-like lists built with the pairing operator $\text{cons}$.

The next proposition ensures that if we consider a non-self-overlapping evaluation rule, then the existence of an occurrence morphism from its left-hand side to a term graph is a sufﬁcient condition for the applicability of the rule, i.e., the pushout complement and the pushout of Figure 3(b) can always be constructed.
Figure 4: The evaluation rules $\mathcal{G}[R_f]$ and $\mathcal{G}[R_{cdr}]$.

**Proposition 17** (existence of pushout complements and pushouts). Let $p = (L \xleftarrow{l} K \xrightarrow{r} R)$ be an evaluation which is not self-overlapping, and let $g : L \rightarrow G$ be an occurrence morphism. Then in category $\text{TGraph}$ there exists a pushout complement $\langle D, k : K \rightarrow D, d : D \rightarrow G \rangle$ of $\langle l, g \rangle$, where $D$ is obtained from graph $G$ by making the labeling and the successor function undefined on the image of the root of $L$.

Moreover, a pushout $\langle H, h : R \rightarrow H, b : D \rightarrow H \rangle$ of the resulting arrow $k : K \rightarrow D$ and $r$ always exists, and therefore in the above hypotheses there exists a direct derivation $G \Rightarrow p, g, H$.

The proof of the last proposition is reported (for the equivalent category $\text{Jungle}$) in [10], where also general conditions for the existence of pushouts are presented. It is worth stressing that in the hypotheses of the last proposition, the pushout complement object $D$ has the same nodes of $G$; thus the nodes of $G$ can be “traced” after the rewriting. More formally, there is a total function, called the **track function** $\text{tr} : N_G \rightarrow N_H$, defined as $\text{tr}(n) = b(n)$ for all $n \in N_G$ ($= N_D$).

## 5 Adequacy of algebraic term graph rewriting for rational parallel term rewriting

The relationship between term and term graph rewriting has been nicely formalized in [23] with the notion of **adequate mapping** between rewriting systems. We recall here the definition, referring to that paper for the precise motivations. A **rewriting system** is defined in this context as a triple $(A, R, S)$, where $A$ is a set of states (in our case terms or graphs), $R$ is a set of rules, and $S$ is a set of reduction sequences, closed under certain operations.

**Definition 18** (adequate mapping between rewriting systems). Let $(A_1, R_1, S_1)$ and $(A_2, R_2, S_2)$ be two rewriting systems. A mapping $\mathcal{U} : A_1 \rightarrow A_2$ is **adequate** if:

- [Surjectivity] $\mathcal{U}$ is surjective;
- [Preservation of normal forms] $a \in A_1$ is in normal form iff $\mathcal{U}[a] \in A_2$ is in normal form;
- [Preservation of reductions] If $a \rightarrow^* a'$ with a reduction sequence in $S_1$, then $\mathcal{U}[a] \rightarrow^* \mathcal{U}[a']$ with a reduction sequence in $S_2$.

---

3Without this condition the statement would not be true, because the identification condition [16] may not be satisfied.

4An interesting fact, which is not relevant for this paper, is that the pushout of two arrows exists in $\text{TGraph}_e$ iff the associated substitutions unify, and in this case the pushout is a most general unifier.

5A state is in normal form if there is no reduction sequence starting from it.

6We consider only reduction sequences of finite length.
[Cofinality] For $a \in A_1$ and $b \in A_2$, if $\mathcal{U}[a] \to^* b$ in $S_2$, then there is an $a'$ in $A_1$ such that $a \to^* a'$ in $S_1$ and $b \to^* \mathcal{U}[a']$ in $S_2$.

We show below that the unraveling function $\mathcal{U}$ introduced in the previous sections is an adequate mapping from a given orthogonal TGRS $\mathcal{P}$ to its unraveled orthogonal TRS $\mathcal{U}[\mathcal{P}]$, restricting the allowed parallel reduction sequences to the rational ones. Intuitively, the restriction to rational parallel reductions is justified by the fact that an occurrence of an evaluation rule $\rho$ in a term graph $G$ induces a possibly infinite, but certainly rational parallel redex in the term obtained by unraveling $G$.

**Definition 19** (rational parallel reduction sequences). Let $\mathcal{R}$ be an orthogonal TGR. A parallel reduction $t \to_\Phi t'$ is **rational** if the term obtained by marking in $t$ all the occurrences of redexes of $\Phi$ is rational. A rational **parallel reduction sequence** is a parallel reduction sequence where each step is rational. A rational TRS is a triple $(CT_{rat} \mathcal{R}, \mathcal{R}_{rat}(\mathcal{R}))$, where $CT_{rat}$ is the set of all rational terms in $CT_{\mathcal{R}}$, $\mathcal{R}$ is an orthogonal TRS where all right-hand sides are rational terms, and $\mathcal{R}_{rat}(\mathcal{R})$ is the set of all rational parallel reduction sequences using rules in $\mathcal{R}$.

It is worth stressing that strong confluence and confluence (Proposition 7) also hold for rational parallel reductions.

In order to prove the adequacy of the unraveling function, we need the following fundamental result, which formalizes the “parallel interpretation” discussed in the introduction: A single (possibly cyclic) term graph reduction can be interpreted as a parallel (possibly infinite) term reduction.

**Theorem 20** (from graph reductions to parallel term reductions). Let $p = (L \leftarrow K \rightarrow R)$ be a non-self-overlapping evaluation rule, let $G$ be a term graph, and let $g : L \rightarrow G$ be an occurrence morphism. By Proposition 7 we know that $G \Rightarrow_{p,g} H$, with the corresponding track function $tr : N_G \rightarrow N_H$. Then for each node $n \in N_G$, we have

$\mathcal{U}_G[n] \rightarrow_\Phi \mathcal{U}_H[tr(n)] \sigma$

where $\Phi$ is the (possibly infinite) parallel redex $\Phi = \{(\mathcal{G}(\pi), \mathcal{U}[p]) \mid \pi$ is a path in $G$ from $n$ to $g(\underline{n})\}$ ($\underline{n}$ is the root of $L$), and where substitution $\sigma : \var(G) \rightarrow \var(G)$ is defined as $\sigma(x) = y$ if $y \in \var(G) \land tr(y) = x$, and $\sigma(x) = \bot$ if $\exists y \in \var(G), tr(y) = x$.

**Proof.** For the sake of simplicity, let us assume that $\var(G) = \emptyset$, which implies that substitution $\sigma$ becomes $\sigma = \bot$ for all $x \in \var(H)$.\footnote{The general case needs an additional technical lemma showing that the trace function maps variables to variables in an injective way (thus $\sigma$ is well-defined); this can be proved by a careful inspection of the double-pushout diagram.}

Let $R : l_p \rightarrow r_p$ be the rewrite rule $\mathcal{U}[p]$. We first have to show that $\Phi$ is a parallel redex of $\mathcal{U}_G[n]$, i.e., that for each $(\mathcal{G}(\pi), R) \in \Phi$, there is a substitution $\tau$ such that $\mathcal{U}_G[n]/\mathcal{G}(\pi) = l_p \tau$. In fact we have

$\mathcal{U}_G[n]/\mathcal{G}(\pi) = \{\text{because } \pi \text{ is a path from } n \text{ to } g(\underline{n}) \text{ (see Definition 10)}\}$

$\mathcal{U}_G[g(\underline{n})] = \{\text{by point 1 of Proposition 11 and by Definition 15}\}$

Thus all redexes in $\Phi$ are realized by the same substitution $\sigma_g$. Let $W$ be the set of all occurrences of paths from $n$ to $g(\underline{n})$ in $G$ (thus $W$ is the set of all occurrences of redexes in $\Phi$), and let $\{w_1, w_2, \ldots\}$ be an arbitrary but fixed enumeration of $W$ such that if $w_i < w_j$, then $i < j$ (in words, no occurrence can be followed by one of its prefixes). For all $i < \omega$, define

$t_i(u) = \begin{cases} 
\mathcal{U}_G[n](u) & \text{if } \forall j > i. u \not\geq w_j \\
\bot & \text{otherwise.}
\end{cases}$
Obviously, $\{t_i\}_{i<\omega}$ is a chain and $\bigcup_{i<\omega} \{t_i\} = \mathcal{U}_G[n]$. Furthermore, chain $\{t_i\}_{i<\omega}$ satisfies the conditions of Definition\([5]\) by orthogonality, $(w_j,R)$ is a redex of $t_i$ if $j \leq i$, while $t_i(w_j) = \perp$ if $j > i$; and the subset $\Phi_i$ of $\Phi$ including all redexes of $t_i$ is finite (more precisely, $\Phi_i = \{(w_1,R),\ldots,(w_i,R)\}$, and in particular $\Phi_0 = \emptyset$). Thus by Definition\([5]\) we have $\mathcal{U}_G[n] \to_\Phi \bigcup_{i<\omega} \{s_i\}$, where, for each $i$, $t_i \to_\Phi s_i$.

It remains to prove that $\bigcup_{i<\omega} \{s_i\} = \mathcal{U}_H[tr(n)]\sigma$. Let us first show by induction that $\forall i < \omega. s_i \leq \mathcal{U}_H[tr(n)]\sigma$.

**[Base Case]** Since $\Phi_0 = \emptyset$, we have that $s_0 = t_0$. Let $u \in \Theta(s_0)$. By definition $u \not\supseteq w$ for all $w \in W$. Thus we have

$$s_0(u) = \mathcal{U}_G[n](u) = \begin{cases} \text{assuming that } \pi \text{ is the only path from } n \text{ to } n' \text{ in } G \text{ with occurrence } u, \text{ and since } \text{var}(G) = \emptyset \\ l_G(n') \text{ by the explicit definition of } D \text{ (Proposition\([17]\),} \\
\text{since } n' \neq g[u] \end{cases}$$

$$l_H(b(n')) = l_H(tr(n'))$$

$$l_H(tr(n))(u) = [\sigma \text{ does not affect occurrences of operators, like } u]$$

**[Inductive Case]** We must show that $s_i \leq \mathcal{U}_H[tr(n)]\sigma \Rightarrow s_{i+1} \leq \mathcal{U}_H[tr(n)]\sigma$. By the above definitions, the only redex of $t_{i+1}$ which is not of $t_i$ is $\Delta_{i+1} = (w_{i+1},R)$. If $t_{i+1} \to_{\Phi_i} t'$, let $\Delta_{i+1} \setminus \Phi_i$ be the residual, and let $V = \{v_1,\ldots,v_k\}$ its set of occurrences. Then, if $\tau$ is the substitution such that $l_\tau^{n'} = t_{i+1}/v$ for all $v \in V$\(^9\), a careful inspection reveals that $s_{i+1}$ can be defined in term of $s_i$ as

$$s_{i+1}(u) = \begin{cases} s_i(u) & \text{if } u \in \Theta(s_i) \\
\emptyset^{\perp} & \text{if there is a } v \in V \text{ such that } u = vw, \text{ and } w \in \Theta(r_\tau) \\
\perp & \text{otherwise.} \end{cases}$$

Exploiting the induction hypothesis, it remains to show that $s_{i+1}(vw) = \mathcal{U}_H[tr(n)]\sigma(vw)$ only for $v \in V$ and $w \in \Theta(r_\tau)$. This can be done by combining the techniques used for the acyclic case in \([20,10]\), and those used for the Base Case above, because the definition of $t_{i+1}$ ensures that no redex of $\Phi$ appears in substitution $\tau$ (although $\tau$ may substitute an infinite term for a variable).

Finally it remains to prove that $\mathcal{U}_H[tr(n)]\sigma \leq \bigcup_{i<\omega} \{s_i\}$, and this can be done as follows. If rule $R$ is not collapsing, it can be shown that $\bigcup_{i<\omega}\{s_i\}$ is a total term (and therefore it is a maximal element of the approximation ordering), because the least depth of $\perp$’s in $s_i$ tends to infinity. If instead $R$ is collapsing, then it is easy to check that $s_0 = s_1 = \ldots = \bigcup_{i<\omega}\{s_i\}$, and that $\mathcal{U}_H[tr(n)]\sigma = s_0$ using the Base Case above and the fact that the only variable in $H$, $tr(g[n])$, is substituted for $\perp$ by $\sigma$. \(\square\)

Exploiting this main result, we can prove the adequacy of the unraveling function. One minor problem is due to the fact that the unraveling of a term graph is not a term, but a set of terms. Thus either we consider TRS where a state can be a set of terms (which seems quite unnatural), or we have to consider pointed term graphs, i.e., graphs with a distinguished node, and to assume that the $\mathcal{U}$ unravels each graph at that specific node. However, in this last case, unraveling would not preserve normal forms, because a graph may contain a redex in a part that is not reachable from the distinguished node (in the garbage), and such redex would not appear in the unraveled term. Full adequacy could be recovered by adding garbage collection at each graph rewriting step (as it is done in [5][23]) but we prefer to prove a slightly weaker result without modifying the graph rewriting formalism.

---

\(^8\)It is worth recalling that $t \leq t' \Leftrightarrow \forall u \in \Theta(t). t(u) = t'(u)$.

\(^9\)It can be checked that all redexes in $\Delta_{i+1} \setminus \Phi_i$ are realized by the same substitution in $t'$. 
Theorem 21 (adequacy of TGR for rational parallel TR). Given an orthogonal TGRS \( \mathcal{S} \), let \((\mathcal{G}, \mathcal{P}, \mathcal{I}(\mathcal{P}))\) be the rewriting system where \( \mathcal{G} \) is the set of all pointed term graphs over \( \Sigma \) and \( \mathcal{I}(\mathcal{P}) \) is the set of all graph reduction sequences using rules in \( \mathcal{P} \) and such that the track function preserves the distinguished node.

Then the unraveling function \( \mathcal{U} \) is a mapping from \((\mathcal{G}, \mathcal{P}, \mathcal{I}(\mathcal{P}))\) to the rational TRS \((CT_\Sigma^{rat}, \mathcal{U}[\mathcal{P}], \mathcal{I}_{rat}(\mathcal{U}[\mathcal{P}]))\) which satisfies all the conditions of adequate mappings (Definition 18), except of the preservation of normal forms. Nevertheless, it satisfies the following weaker version: [Weak preservation of normal forms] if \( a \in A_1 \) is a normal form, then so is \( \mathcal{U}[a] \in A_2 \).

Proof. According to Definition 18 we have:

[Surjectivity] Immediate by Definition 10 using pointed graphs.

[Weak preservation of normal forms] Follows from point 2 of Proposition 11 if there is a redex of rule \( \mathcal{U}[p] \) in term \( \mathcal{U}[G] \), then there is an occurrence morphism from the left-hand side of \( p \) to \( G \).

[Preservation of reductions] By repeated applications of Theorem 20.

[Cofinality] Let \( G \) be a pointed graph, and suppose that \( \mathcal{U}[G] \rightarrow^* t \) via a rational reduction sequence.

We show by induction on the length of the sequence that there is a \( \mathcal{G}' \) such that \( t \rightarrow^* \mathcal{U}[\mathcal{G}'] \), and \( \mathcal{G} \Rightarrow^* \mathcal{G}' \).

[Base Case] If \( \mathcal{U}[G] \rightarrow_\Phi t \) and \( \Phi \) is rational, it is possible to show that there exists a finite set \( M \) of occurrence morphisms of rules of \( \mathcal{P} \) in \( \mathcal{G} \), such that their “unraveling” (that we do not define formally) \( \mathcal{U}[M] \) is a parallel redex of \( \mathcal{U}[G] \) containing \( \Phi \). Then let \( \mathcal{G}' \) be the graph obtained by applying to \( \mathcal{G} \) all the occurrence morphisms in \( M \) in any order (by orthogonality \( \mathcal{G}' \) is well-defined). Then it can be shown that \( t \rightarrow \mathcal{U}[M] \Phi \mathcal{U}[G'] \).

\( \mathcal{U}[G] \xrightarrow{r'} \xrightarrow{d} \mathcal{U}[G'] \)

\( \Phi \)

\( t \)

\( \Phi \backslash d \)

\( \mathcal{U}[G'''] \)

\( G \Rightarrow^* G' \Rightarrow^* G'' \)

[Inductive Case] Suppose that \( \mathcal{U}[G] \rightarrow^n t' \rightarrow_\Phi t \), and consider the diagram above. By inductive hypothesis there exists \( \mathcal{G}' \) such that \( G \Rightarrow^* \mathcal{G}' \) and \( t' \rightarrow^* \mathcal{U}[\mathcal{G}'] \). By strong confluence of rational parallel reductions, there exists a \( t'' \) such that the square commutes, and the residual \( \Phi \backslash d \) is a rational parallel redex. Then applying the Base Case to \( \mathcal{U}[\mathcal{G}'] \rightarrow_{\Phi \backslash d} t'' \), we have that there exists a \( \mathcal{G}'' \) such that \( \mathcal{G}' \Rightarrow^* \mathcal{G}'' \) and \( t'' \rightarrow^* \mathcal{U}[\mathcal{G}''] \).

Example 22 (Rewriting steps). The diagram below shows a few direct derivations using the evaluation rule \( \mathcal{G}[R_{cdr}] \) of Example 16. The corresponding track functions are uniquely determined by the dotted arrows and the fact that the cons node is preserved. Unraveling the four graphs at the nodes \( \circ \), we get the following terms: \( t_0 = \mathcal{U}_{G_0}[\circ] = cdr(cons(f(a), cdr(cons(f(a), cdr(\ldots))))), t_1 = \mathcal{U}_{G_1}[\circ] = t_0, t_2 = \mathcal{U}_{G_2}[\circ] = cdr(cons(f(a), \top)), \) and \( t_3 = \mathcal{U}_{G_3}[\circ] = L. \) By Theorem 20 each direct derivation \( G_i \Rightarrow G_j \) corresponds to a rational parallel reduction \( \mathcal{U}_{G_i}[\circ] \rightarrow_{\Phi_k} \mathcal{U}_{G_j}[\circ] \): it is easy to check that the four rational parallel redexes are \( \Phi_1 = \{\lambda\}, \Phi_2 = \{12(12)^*\}, \Phi_3 = \{(12)^*\} \) and \( \Phi_4 = \{\lambda\}. \) To conclude, note that
if we consider also the evaluation rule $G[R_f]$ of Example [16] then term graph $G_3$ is not a normal form, while $t_3 = \mathbb{W}_{G_3}[\sigma] = \bot$ is, showing that unraveling does not reflect normal forms in general.

6 Conclusions

We showed that by exploiting the complete partial ordered structure of (infinite, partial) terms, a notion of infinite parallel reduction can be defined. Moreover, we proved that this notion can be used to relate term graph rewriting with cycles and term rewriting, formalizing the intuition that a single graph reduction correspond to a (possibly infinite) parallel term reduction. This result is used to show that cyclic graph rewriting is adequate for rational term rewriting, exploiting the notion of adequacy proposed in [23].

As discussed in the introduction, for several approaches to cyclic term graph rewriting it is pretty clear whether this parallel interpretation is more faithful than the sequential one: this point has still to be clarified for the more recent approaches, and it will be addressed in the full version of the paper. Another interesting topic to explore is how far and under which additional restrictions the proposed results could be generalized to non-orthogonal systems.
