Abstract

We extend the construction of Calabi-Yau manifolds to hypersurfaces in non-Fano toric varieties, requiring the use of certain Laurent defining polynomials, and explore the phases of the corresponding gauged linear sigma models. The associated non-reflexive and non-convex polytopes provide a generalization of Batyrev’s original work, allowing us to construct novel pairs of mirror models. We showcase our proposal for this generalization by examining Calabi-Yau hypersurfaces in Hirzebruch $n$-folds, focusing on $n = 3, 4$ sequences, and outline the more general class of so-defined geometries.

1 Incentives, results and summary

A recent study [1] generalized the well-known Calabi-Yau complete intersections of hypersurfaces in products of projective spaces [2, 3, 4] so as to allow certain of the hypersurface defining equations to have negative degrees over some of the factor projective spaces, and so necessarily use Laurent (rational) monomials amongst the defining equations [1, 5]. Given the novelty of such models and the physics phenomena they exhibit already within the \((m \geq 0)\) infinite sequence of hypersurfaces in Hirzebruch \(n\)-folds \(\mathcal{F}_m^{(n)}\), in Section 2 we analyze the gauged linear \(\sigma\)-model (GLSM) world-sheet field-theory [8, 9] corresponding to these sequences, focusing on \(n = 3, 4\). We also map out the associated enlarged (complete) Kähler moduli space, i.e., “phases,” by considering all possible triangulations of the spanning polytope (and its convex hull) associated to the embedding non-Fano toric variety.

In order to analyze the GLSM ground states, which form a toric variety, the secondary fan [8, 10, 11, 12, 13], in Section 3 we generalize the toric methods [14, 15, 16, 17, 18, 19] to cases where Laurent superpotentials naturally appear in the defining equations of the (Calabi-Yau) subvarieties. In particular, our extension includes a large class of non-convex and possibly self-crossing (VEX) polytopes and corresponding fans, which contain flipped, i.e., reversely oriented cones (faces). We then show that such generalizations: \((a)\) produce Laurent monomials in the defining equations of transversal\(^2\) Calabi-Yau hypersurfaces, and \((b)\) automatically realize natural pairs of mirror Calabi-Yau \(n\)-folds generalizing earlier results [20, 21, 22], associated to “trans-polar” pairs of VEX polytopes.

In Section 4 we explicitly compute the Euler and Hodge numbers of the Calabi-Yau hypersurfaces in \(\mathcal{F}_m^{(n)}\) to demonstrate that these key numerical invariants of the trans-polar pairs of oriented VEX polytopes \((a)\) evaluate exactly as they do for convex polytopes, and \((b)\) exhibit all requisite aspects of the mirror relations. Section 5 summarizes our results and concluding comments, while computational details are collected in the appendices. While this proof-of-concept paper illustrates the various toric geometry techniques by focusing on Hirzebruch \(n\)-folds [5] and their Calabi-Yau hypersurfaces, more general examples and further details may be found in the companion paper [23].

2 The gauged linear sigma model

Recent work [1, 5] has shown that there are significant merits to constructing Calabi-Yau algebraic varieties at least some of the defining equations of which contain Laurent monomials,

\[^1\] Using methods of classical algebraic geometry [6, 7], we have found that the classical topological data of certain sequences of such constructions exhibit a periodicity [5], which is broken by quantum effects. Since classical physics models on the Calabi-Yau hypersurfaces in the Hirzebruch \(n\)-fold \(\mathcal{F}_m^{(n)}\) are equivalent to those in \(\mathcal{F}_{m+n}^{(n)}\), respectively, the transformation \(\mathcal{F}_m^{(n)} \rightarrow \mathcal{F}_{m+n}^{(n)}\) is a classical (discrete) symmetry. Its breaking by quantum effects such as instanton numbers [5] then represents a novel (stringy) quantum anomaly.

\[^2\] A function \(f(x)\) is transversal if \(f(x) = 0\) and \(df(x) = 0\) have no common solution other than the “base-locus” (such as \(x = 0\)); we then also refer to the zero-locus \(f^{-1}(0) := \{x : f(x) = 0\}\) as being transversal. Throughout this paper, we focus on this distinctly algebraic quality, and defer its relation to the subtler complex-analytic property of smoothness (related to Cauchy-Riemann conditions and similar) for later.
and that standard methods of algebraic geometry and cohomological algebra can be adapted to compute the requisite classical data. For applications in string theory and its M- and F-theory extensions, it is desirable to find a world-sheet field theory model with such target spaces.

For well over two decades now, the standard vehicle to this end is Witten’s gauged linear sigma model (GLSM) [8, 24, 25], where fermionic integration leaves a potential for the scalar fields of the general form:

\[ U(x_i, \sigma_a) = \sum_i |F_i|^2 + \frac{1}{2e^2} \sum_a D_a^2 + \frac{1}{2} \sum_{a,b} \sigma_a \sigma_b \sum_i Q_i^a Q_i^b |x_i|^2, \]

\[ D_a = -e^2 \left( \sum_i Q_i^a |x_i|^2 - r_a \right). \]  

(1a) \hspace{5cm} (1b)

Here \( \sigma_a \) is the scalar field from the \( a \)th gauge twisted-chiral superfield, \( x_i \) and \( F_i \) are respectively the scalar and auxiliary component fields from the \( i \)th “matter” chiral superfield \( X_i \), \( Q_i^a \) is the charge of the \( i \)th chiral superfield with respect to the \( a \)th \( U(1) \) gauge interaction, and the \( r_a \) are the contributions from the Fayet-Iliopoulos terms. In supersymmetric theories and especially when acting on chiral superfields, gauge groups are typically complexified and the GLSM naturally has \( U(1, \mathbb{C}) \simeq \mathbb{C}^* \) actions — which are the “torus actions” in the toric geometry of the space of ground-states in the GLSM.

### 2.1 Laurent superpotentials

For illustration, consider the GLSM models with the superpotential\(^3\)

\[ W(X) := X_0 \cdot f(X), \]

\[ f(X) := \sum_{j=1}^{2} \left( \sum_{i=2}^{n} \left( a_{ij} X_i^n X_{n+i}^{2-m} + a_j X_i^n X_{n+i}^{(n-1)m+2} \right) \right), \]

(2a) \hspace{5cm} (2b)

where \( m, n > 1 \) are integers and \( X_0 \) is the chiral superfield that in some ways serves as a Lagrange multiplier; we focus on \( n = 2, 3, 4 \), but generalizations are straightforward. Such superpotentials are strictly invariant with respect to the \( U_1(1) \times U_2(1) \) gauge symmetry with the charges

\[ Q_1(X_0; X_1, X_2 \cdots, X_n, X_{n+1}, X_{n+2}) = (-n; 1, 1, \cdots, 1, 0, 0), \]

\[ Q_2(X_0; X_1, X_2 \cdots, X_n, X_{n+1}, X_{n+2}) = (m-2; -m, 0, \cdots, 0, 1, 1). \]

(3a) \hspace{5cm} (3b)

Manifestly, for \( m > 2 \), the \( a_{ij} \)-terms become Laurent monomials; as we will see below in more detail, this turns out to be closely related to the models considered in Ref. [1, 5]. For now, we discuss the GLSM with the potential (1a) in its own right, being especially interested in the novelty of the \( m > 2 \) cases.

The standard requirement for the superpotential to be chiral is straightforwardly satisfied:

\[ \bar{D}_{\hat{a}} W(X) = f(X) \left( \bar{D}_{\hat{a}} X_0 \right) + \sum_{i=1}^{n+2} X_0 \frac{\partial f(X)}{\partial X_i} \left( \bar{D}_{\hat{a}} X_i \right) = 0, \]

(4)

owing to the fact that \( X_0 \) and all \( X_i \)'s are chiral superfields, and regardless of the fact that the chiral superfields \( X_{n+1} \) and \( X_{n+2} \) appear with negative powers for \( m > 2 \): As we will

---

\(^3\)This is not the most generic superpotential but the natural generalization of Fermat-like potentials for the current class of models we are considering; see below.
show below, the background values (vev’s) of the lowest component fields in $X_0, X_i$ are always restricted so that the vev’s of $f(X)$ and $X_0 \frac{\partial f(X)}{\partial X_i}$ remain finite, even in the cases when $\langle X_{n+j} \rangle \to 0$. Eq. (4) then insures that the superpotential (2) is itself a chiral superfield and all manifest supersymmetry methods apply; we therefore proceed as usual. In addition, this also makes this superpotential regular in all component fields, and so insures that (2) specifies a well-defined field theory.\footnote{While completing this article, we have learned from Lara Anderson and James Gray of their as yet unpublished exploration of similar superpotentials, in the context of adapting the GLSM to the gCICYs \cite{gCICYs}; it is our understanding that our two analyses are mutually consistent, complementary and corroborating.}

### 2.2 The ground state

The potential (1a) is a sum of positive-definite terms, each of which has to vanish separately in the ground state. The first four groups of constraints stem from the vanishing of the $F$-terms, for which the equations of motion give $F_i = \frac{\partial W}{\partial x_i}$:

\[
\left| \frac{\partial W(x)}{\partial x_0} \right|^2 \equiv 0,
\]

\[
= \sum_{j=1}^{2} \left( \sum_{i=2}^{n} a_{ij} x_i^n x_{n+j}^{2-m} + a_{j} x_1^n x_{n+j}^{(n-1)m+2} \right)^2 = 0,
\]

\[
= \left| \frac{\partial W(x)}{\partial x_1} \right|^2 = \left| x_0 \right|^2 \left( \sum_{j=1}^{2} a_{j} x_{n+j}^{2-m} \right)^2 = 0, \quad i = 2, \ldots, n;
\]

\[
= \left| \frac{\partial W(x)}{\partial x_{n+j}} \right|^2 = \left| x_0 \right|^2 \left( 2-m \sum_{i=2}^{n} a_{ij} x_i^n x_{n+j}^{1-m} + a_{j} x_1^n x_{n+j}^{(n-1)m+2} \right)^2 = 0, \quad j = 1, 2;
\]

The vanishing of the last term in (1a) imposes:

\[
\left| (-n)\sigma_1 + (m-2)\sigma_2 \right|^2 \left| x_0 \right|^2 + \left| \sigma_1 + (-m)\sigma_2 \right|^2 \left| x_1 \right|^2 + \left| \sigma_1 \right|^2 \sum_{i=2}^{n} \left| x_i \right|^2 + \left| \sigma_2 \right|^2 \sum_{j=1}^{2} \left| x_{n+j} \right|^2 = 0.
\]

This identifies the “normal mode” linear combinations: $U_3(1)$ generated by $mQ_1+Q_2$ with respect to which $x_1$ is neutral, and $U_4(1)$ generated by $(m-2)Q_1+nQ_2$ with respect to which $x_0$ is neutral.

Finally, the vanishing of the $D$-terms (1a) impose:

\[
\frac{e^2}{2} \left( -n |x_0|^2 + \sum_{i=1}^{n} |x_i|^2 - r_1 \right)^\frac{1}{2} = 0,
\]

\[
\frac{e^2}{2} \left( (m-2) |x_0|^2 - m |x_1|^2 + \sum_{j=1}^{2} |x_{n+j}|^2 - r_2 \right)^\frac{1}{2} = 0.
\]
2.3 Phases

We now turn to analyze the D-term constraints (6), following [13]. The $U(1)$ charges $Q_i^r$ of the chiral superfields, $(X_0, X_i)$, determine the two-dimensional secondary fan (phase diagram) given in Figure 1\textsuperscript{5}. In particular, we can find the phase-boundaries by determining the conditions for the $U_r$ phase; the "\textsuperscript{····}" entries are generally nonzero and are outside the Stanley-Reisner ideal.

Figure 1: The phase diagram of the GLSM with the Calabi-Yau $n$-fold $\mathfrak{F}_{m}^{(n)}$ "geometric" phase; the "*" entries are generally nonzero and are outside the Stanley-Reisner ideal.

conditions for the $U(1)^2 \rightarrow U(1)$ gauge symmetry breaking. When\textsuperscript{6} (i): $x_0 = 0 = x_i$ for $i = 1, \ldots, n$ but $x_{n+j} \neq 0$ for $j = 1, 2$, the $U_1(1)$ gauge group is preserved but $U_2(1)$ is broken completely. In this case (6a) and (6b) imply that $r_1 = 0$ and $r_2 \geq 0$, respectively; this happens along the $(0,1)$-direction in the $(r_1, r_2)$-plane. Similarly, (ii): $U_2(1)$ is preserved when $x_0 = 0 = x_1 = x_{n+1} = x_{n+2}$ but $x_i \neq 0$ for $i = 2, \ldots, n$, while $U_1(1)$ is broken completely. Then, $r_2 = 0$ and $r_1 \geq 0$ from (6b) and (6a), respectively; this happens along the $(1,0)$-direction. Next, (iii): if only $x_1 \neq 0$, the combined $U_3(1)$ gauge symmetry generated by the charges $mQ_1+Q_2$ is preserved, so (6a) constrains $r_1 \geq 0$ and the D-term from this $U_3(1)$ implies that $mr_1+r_2 = 0$; this happens along the $(1,-m)$-direction. Finally, (iv): if only $x_0 \neq 0$, the combination $U_4(1)$ gauge symmetry generated by the charges $(m-2)Q_1+nQ_2$ is preserved. The corresponding D-term constraint, in terms of the corresponding combination of (6a) and (6b), implies that $(m-2)r_1+n r_2 = 0$. Also, (6a) then implies that $r_1 \leq 0$; this happens along the $(-n,(m-2))$-direction.

Thus, there are four different phases, as depicted in Figure 1. We now analyze them in turn, using that a ground state solution must also satisfy the $F$-term constraints (5).

**Phase I:** $r_1, r_2 > 0$. The $F$-term constraints are solved by having $x_0 = 0$ and $f(x) = 0$. From the $D$-term analysis above, the *excluded* region in the field-space

$$
\mathcal{F}_I = \{x_1 = \ldots = x_n = 0\} \cup \{x_{n+1} = x_{n+2} = 0\}
$$

\textsuperscript{5}The analysis of the secondary fan, referred to as the enlarged Kähler moduli space can also be done by first considering the toric variety, $X$, which is the ambient space for the Calabi-Yau hypersurface, for more details, see section 3. There are four different triangulations of the associated spanning polytope $\Delta_X$, not necessarily containing all of the points in $\Delta_X$, which allows us to obtain the large radius Calabi-Yau phase as well as the Landau-Ginzburg orbifold [12].

\textsuperscript{6}For the remainder of this section, we omit writing the vacuum expectation bra-kets for brevity, so "$x_i = 0$" will denote the vanishing of the vev $(x_i)$, not the field.
is exactly the Stanley-Reisner (or irrelevant [18]) ideal for the Hirzebruch \( n \)-fold \( \mathcal{F}_m^{(n)} \) \((m\)-twisted \( \mathbb{P}^{n-1} \)-bundle over \( \mathbb{P}^1 \)). Since the \( x_{n+j} \) cannot both vanish (5e) implies that \( \sigma_2 = 0 \). Eq. (5e) then simplifies and implies that \( \sigma_1 = 0 \) since the \( x_i, i = 1, \ldots, n \) cannot all be zero. Thus, \( f(x) = 0 \) defines a Calabi-Yau \((n-1)\)-fold hypersurface in \( \mathcal{F}_m^{(n)} \).

Direct computation shows that the polynomial \( f(x) \) is transversal for generic choices of \( a_{ij}, a_j \), so that its \( n+2 \) gradient components \( \frac{\partial f}{\partial x_i}, \frac{\partial f}{\partial x_{n+j}} \) vanish simultaneously with \( f(x) \) itself only within the excluded region (7), see Appendix A for more details.

**Phase II:** \(-mr_1 < r_2 < 0\). The \( F \)-term constraints are still solved by having \( x_0 = 0 \) and \( f(x) = 0 \). From the \( D \)-term analysis above, the excluded region in the field-space

\[
\mathcal{J}_{II} = \{ x_1 = 0 \} \cup \{ x_2 = \ldots = x_{n+2} = 0 \}
\]

is the Stanley-Reisner ideal for the weighted projective space \( \mathbb{P}^{n}_{(m; \ldots; m; 1:1)} \) in terms of the coordinates \( x_2, \ldots, x_{n+2} \). With \( x_1 \neq 0 \), (5e) implies that \( \sigma_1 = m\sigma_2 \), and since the remaining \( x_i \) cannot all vanish simultaneously, it follows that \( \sigma_1 = \sigma_2 = 0 \). Thus, \( f(x) = 0 \) defines the MIPC-desingularization of the Calabi-Yau \((n-1)\)-fold hypersurface \( \mathbb{P}^{n}_{(m; \ldots; m; 1:1)}[(n-1)m+2] \).

Indeed, Eqs. (6a) and (6b) imply that (recall that \( r_2 < 0 \))

\[
|x_1| = \sqrt{\frac{\sum_j |x_{n+j}|^2 - r_2}{m}} = \sqrt{r_1 - \sum_{i=2}^{n} |x_i|^2} > 0
\]

throughout this phase, and \( x_1 \) parametrizes the exceptional set of the MIPC-desingularization of \( \mathbb{P}^{n}_{(m; \ldots; m; 1:1)} \). Clearly, \( |x_1| \to 0 \) at the boundary (\( ii \)) where \( x_{n+1}, x_{n+2} \) and \( r_2 \) vanish, while \( |x_1| \to \sqrt{r_1} > 0 \) on the boundary (\( iii \)) where \( x_i = 0 \) but \( r_1 > 0 \). It then follows that at the boundary (\( ii \)) the MIPC-desingularization is “blown-down,” leaving the hypersurface \( \mathbb{P}^{n}_{(m; \ldots; m; 1:1)}[(n-1)m+2] \) with the unresolved orbifold singularity — which gives rise to the partially restored \( U_2(1) \) gauge symmetry indicated above.

Within the phase II region and away from its boundaries, both \( U(1) \)-symmetries are completely broken over most of the \( f(x) = 0 \) surface when \( x_1, \ldots, x_n \neq 0 \). However, at special points where some but not all of \( x_1, \ldots, x_n \) vanish, a discrete subgroup of the gauge symmetry may be restored, such as at \((x_1, 0, \ldots, 0, x_{n+1}, \omega x_{n+1})\) with \( \omega^{(n-1)m+2} = -\frac{b_1}{b_2} \) to satisfy (5)–(6); here \( x_{n+1} \neq 0 \) completely breaks \( U_2(1) \), whereupon \( x_1 \neq 0 \) breaks \( U_1(1) \to \mathbb{Z}_n \); these are then “local” \( \mathbb{Z}_n \) orbifold points of the hypersurface \( f(x) = 0 \) — which however is not a global \( \mathbb{Z}_n \)-quotient. Phase II is thus identified as the “orbifold phase” [12, 13].

**Phase III:** \( \frac{m-2}{m} r_1 < r_2 < -mr_1 \). The \( D \)-term constraints imply that now both \( x_0 = 0 \) and \( x_1 = 0 \) must be excluded:

\[
\mathcal{J}_{III} = \{ x_0 = 0 \} \cup \{ x_1 = 0 \}.
\]

Thus, all the \( F \)-term constraints, (5b)-(5a) are solved by setting \( x_i = 0 \) for \( i = 2, \ldots, n+2 \), and (5e) simplifies to

\[
|(-n)\sigma_1 + (m-2)\sigma_2|^2 |x_0|^2 + |\sigma_1 + (-m)\sigma_2|^2 |x_1|^2 = 0.
\]

The vevs \( x_0 \neq 0 \neq x_1 \) break \( U_1(1) \times U_2(1) \to \mathbb{Z}_{m(n-1)+2} \); e.g., \( x_1 \neq 0 \) sets \( \sigma_1 = m\sigma_2 \), producing \( |(m(1-n)-2)\sigma_1|^2 |x_0|^2 = 0 \). Thus, the vacuum solution in phase III is that of a \( \mathbb{Z}_{m(n-1)+2} \) Landau-Ginzburg orbifold of \( f(x) = 0 \), acting with charges \( mQ_1 + Q_2 \).
Phase IV: $0 < r_2 < \frac{m - 2}{n} r_1$. The $D$-term analysis implies that $x_0 = 0$ must now be excluded, whereupon the first two $F$-term constraints, (5b) and (5c), imply that $x_1 = \cdots = x_n = 0$. The remaining $F$-term constraints, (5a) and (5d) turn out to be satisfied, leaving $x_{n+1}, x_{n+2}$ unconstrained. Since $x_1 = 0$, the 2nd $D$-term constraint (6b) produces $\sum_{j=1}^{n} |x_{n+j}|^2 = r_2 + \frac{m - 2}{n} r_1$, which is positive in this phase, so that $x_{n+1} = x_{n+2} = 0$ must also be excluded, and we obtain:

$$\mathcal{I}_{IV} = \{x_0 = 0\} \cup \{x_{n+1} = 0 = x_{n+2}\}.$$  \hspace{1cm} (12)

Since $x_{n+1}, x_{n+2}$ cannot both vanish, their vevs break $U_2(1)$ completely, while $x_0 \neq 0$ breaks $U_1(1) \to \mathbb{Z}_n$ since $Q_1(x_0) = -n$; correspondingly, (5e) reduces to $|(-n)\sigma_1||x_0| = 0$. This then is a hybrid phase in which a Landau-Ginzburg $\mathbb{Z}_n$ orbifold of \{(x, \cdots, x) : f(x) = 0\} is fibered over the base-$\mathbb{P}^1 = \mathbb{P}(x_{n+1}, x_{n+2})$.

At this point let us make the following comment on the vanishing of the $x_i = 0, i > 0$ in the Landau-Ginzburg phase above and the existence of a superpotential with Laurent monomials (2). By going through phase IV, where $x_i = 0$ for $i = 1, \ldots, n$ correspond to the fiber having collapsed to a Landau-Ginzburg orbifold, the Laurent monomials are absent — in fact, $f(x)$ vanishes identically in phase IV. By transitioning to phase III, we then have $x_1 \neq 0$ while $x_2 = \cdots = x_{n+2} = 0$, which is the true Landau-Ginzburg orbifold. On the other hand, when transitioning from phase II, through the boundary (iii), into phase III, we have to specify the multi-limit $x_i, x_{n+j} \to 0$ so that $f(x) = 0$ remains well-defined. To this end,

$$\lim_{x_1 \to 0} f(x) = \sum_{i=2}^{n} \left( \frac{a_{i1}}{x_{m-2}^{i-2}} + \frac{a_{i2}}{x_{m-2}^{i-2}} \right) x_i^n$$  \hspace{1cm} (13)

shows that $x_2, \cdots, x_n$ should vanish sufficiently faster than $x_{n+j}$, except perhaps one of the $x_i$ for which then we must insure that $x_{n+2} = \omega x_{n+1} \to 0$ with $\omega^{m-2} = \frac{-a_{i2}}{a_{i1}}$.

The phases and their boundaries are summarized in Table 1. The vevs of $x_0$ and $x_1$

| $Q_1$ | $Q_2$ | Fiber | Base | Gauge Group | Phase Region |
|-------|-------|-------|-------|-------------|--------------|
| $-n$ | $m-2$ | 1 0 1 0 | 0 0 | $U_1(1)$ | $U_2(1)$ $(r_1, r_2)$-plane |
| $i$ | $I$ | $ii$ | $II$ | $iii$ | $\sqrt{\frac{m}{n}} = \sqrt{r_1}$ | $U_3(1) \times \mathbb{Z}_M^+$ | $r_1 > 0, r_2 > -mr_1$ |
| $I$ | $ii$ | see (9) | $\sqrt{\frac{m}{n}} = \sqrt{r_1}$ | $U_3(1) \times \mathbb{Z}_M^+$ | $r_1 > 0, r_2 > -mr_1$ |
| $III$ | $iv$ | $IV$ | $\sqrt{-\frac{m}{n}} = \sqrt{r_1}$ | $\frac{r_2}{n} r_1 > r_2 > -mr_1$ |

*Generically, the $U(1)^2$ is completely broken, but is “restored” to a discrete subgroup at special points.
†The combination $U_3(1)$ is generated by $mQ_1 + Q_2$, whereas $U_3(1)$ is generated by $(m-2)Q_1 + nQ_2$
‡$M = (n-1)m + 2$: in $iii$, $x_1 \neq 0$ breaks $U_3(1) \to \mathbb{Z}_m$; in $iv$, $x_0 \neq 0$ breaks $U_3(1) \to \mathbb{Z}_m$.
change continuously as \((r_1, r_2)\) are varied through the cycle of phases I–II–III–IV–I, so that the secondary fan depicted to the left in Figure 1 is complete as given.

3 The toric geometry of the ground state

We now turn to examine the toric geometry of GLSM ground states defined by Laurent superpotentials such as (2), and exhibit a justification for the inclusion of Laurent monomials in superpotential such as (1a) and its generalizations. In particular, Laurent superpotentials such as (2) motivate a refinement of the standard methods of toric geometry [14, 15, 16, 17, 19, 18], and we first sketch a few basic facts to establish notation and conventions, adapting from [16, 17, 18].

Every compact toric variety may be specified by a complete rational polyhedral fan \(\Sigma\) within a lattice \(N\), which in turn has a lattice spanning polytope \(\Delta^*\), the vertices \(\nu_\rho\) of which are the minimal \(N\)-integral generators of \(\Sigma\), and \(\Delta^*\) is (coarsely) star triangulated by \(\Sigma\) about \((0 \in \Sigma) \in \text{relint} \Delta^*\). Every toric variety also has a Newton polytope \(\Delta\) (in a lattice \(M\) dual to \(N\)), the \(M\)-integral points of which correspond to anticanonical sections, specified as monomials in the so-called Cox variables [26]:

\[
\bigoplus_{\mu_i \in \Delta \cap M} \left( \prod_{\nu_\rho \in \Delta^* \cap N} x_{\rho}^{(\nu_\rho, \mu_i)+1} \right) \mapsto H^0(K^*),
\]

(14)

where \(\langle \ , \ \rangle\) denotes the Euclidean scalar product, and the “+1” in the exponent indicates sections of the anticanonical \((K^*)^+\). For convex Newton polytopes, the spanning polytope \(\Delta^*\) turns out to be the so-called polar polytope:

\[
\Delta^0 := \{ u : \langle v, u \rangle \geq -1, \ v \in \Delta \}. \tag{15}
\]

For reflexive convex polyhedra, the polar operation is involutive: \(\Delta = (\Delta^* = \Delta^0)^\circ\). The “global” nature of the definition (15) also implies that

\[
(\Delta^*)^\circ = \left( \text{Conv}(\Delta^*) \right)^\circ \quad \text{so} \quad ((\Delta^*)^\circ)^\circ = \text{Conv}(\Delta^*),
\]

(16)

where \(\text{Conv}(\Delta^*)\) is the convex hull (envelope) of \(\Delta^*\), rather than \(\Delta^*\) itself. That is, (15) obscures every non-convex detail in \(\Delta^*\). More importantly, for every reflexive convex polyhedron \(\Delta^*\), the \(x_\rho\)-monomials given by \((\Delta^*)^\circ\) always turn out to be regular, and so cannot provide for the Laurent monomials appearing in (2b) for \(m > 2\).

This “non-convexity hiding” nature (16) of the polar operation (15) turns out to be closely correlated with the systematic omission of Laurent \(x_\rho\)-monomials in (14), which is inadequate for constructing Calabi-Yau hypersurfaces in non-Fano \(n\)-folds such as considered recently [1, 5]. We thus seek a twin generalization of both the polar operation (15) and of convex polytopes.

3.1 The generalization

We propose a twin definition of a class of “VEX polytopes” (to include all convex polytopes but also certain non-convex ones\(^8\)), and a “trans-polar” operation amongst them such that:

\(^7\)We use Definition V.4.3 and rely on the subsequent Theorem V.4.5 [17, p.159]. We denote the spanning polytope by \(\Delta^*\), the “*” reminding that the polytope has a star triangulation defined by the fan that it spans.

\(^8\)The generalization includes novel star triangulations of reflexive polytopes, in which non-star simplices are excluded from the triangulation; see below.
A. For every convex polytope $\Delta$, the trans-polar equals the polar: $\Delta^\vee = \Delta^o$.

B. The trans-polar of every VEX polytope is also a VEX polytope.

C. For every VEX polytope $\Delta$, $(\Delta^\vee)^\vee = \Delta$.

To avoid confusion, $\Delta^\vee$ will denote the trans-polar of $\Delta$, while $\Delta^o$ continues to denote its standard polar (15) [14, 15, 16, 17, 18, 19]. Extending (15), we define the trans-polar operation by the following (iterative-recursive) face-by-face procedure:

**Construction 3.1 (trans-polar).** Given an integral polytope $\Delta$, with an integral star-triangulation consisting of only unit-degree, $d(\theta) = 1$, star-simplices, $\theta$: 

1. recursively decompose $\Delta$ into a minimal collection of convex faces $\theta_\alpha$;
2. construct the polar $\theta_\alpha^o$ to each convex face $\theta_\alpha \subset \Delta$ using the boundary version of (15), with “=” in place of “$\geq$”;
3. dually to $\theta_\alpha \subset \Delta$, assemble the $\theta_\alpha^o$’s into $\Delta^\vee$, the trans-polar of $\Delta$.

Here $d(\theta)$ effectively counts the number of unit volume simplices, see also Appendix B for more details. Requirement A is satisfied by design for all convex polytopes: Step 1 halts with $\Delta$ itself, Step 2 produces $\Delta^\vee = \Delta^o$, and there is nothing left for Step 3. Requirements B and C then define the class of VEX polytopes as the maximal closure under the trans-polar operation. By defining the **deficit** of (15):

$$dfc(o, \Delta) := ((\Delta)^o)^o \smallsetminus \Delta,$$

requirement C above is equivalent to requiring the trans-polar operation of Construction 3.1 to have no deficit on VEX polytopes. For any toric variety $X$ and its spanning polytope $\Delta^*_X$, we define the **extension** part of the (complete) Newton polytope\(^9\):

$$\text{xtn}(\Delta_X) := \left(\Delta_X := (\Delta_X^\vee)^\vee\right) \smallsetminus \left((\Delta_X^*_X)^o = \text{Conv}(\Delta_X^*_X)^o\right).$$

We now proceed to give a more explicit form of the conditions on the VEX polytopes and the construction of mirror manifolds in terms of the associated toric varieties.

- Although we have no conclusive explicit definition of VEX polytopes, they are necessarily defined within a lattice $L \simeq \mathbb{Z}^n$ and must have:
  1. a single $L$-integral point, “0”, in the interior of the polytope;
  2. only $L$-integral vertices, and each at minimal Euclidean distance from “0”;
  3. no $k$-face ($k > 0$) in a $k$-plane containing “0”;
  4. a star-triangulation in which $L$-integral points are only at the apex “0” and the base of each star-simplex.

We note that for 2-dimensional polytopes condition 2 implies condition 3, but not so in higher dimensions; also, without convexity, condition 1 does not imply condition 4.

- This generalizes mirror symmetry as applied to Calabi-Yau hypersurfaces constructed from reflexive pairs $(\Delta_X^*, \Delta_X)$, in which the mirror manifold of a generic Calabi-Yau hypersurface $\hat{Z}_f \subset X$, specified by $f(x) = 0$ in a toric variety $X$ with a reflexive (and convex) Newton

\(^9\)The construction can be extended to cases where the star-simplices, $\theta$, have $d(\theta) > 1$ but we restrict to the former case for simplicity. General fan-like structures that include overlapping cones have been discussed and called “multi-fans” in Ref. [27]. However, we limit our analysis here to cases where the $n$-dimensional fans spanned by VEX polytopes cover $\mathbb{R}^n$ effectively once, so we do not need the “multi-” prefix, see also [23].

\(^{10}\)We show below that $\text{xtn}(\Delta_X)$ encodes the Laurent monomials for non-convex VEX polytopes $\Delta_X$. 

polytope $\Delta_X$ is (an MPCP desingularization of) the Calabi-Yau hypersurface $\tilde{Z}_g \subset X$, specified by $g(y) = 0$ in the toric variety $Y$ the Newton polytope of which is $\Delta_Y = \Delta_X^*$ [21, 28]. Define a class of VEX polytopes wherein every pair of trans-polar polytopes defines a pair of trans-polar toric varieties,

$$(X, Y) : (\Delta_X^*, \Delta_X) = ((\Delta_X)^\vee, (\Delta_X^*)^\vee) = ((\Delta_Y)^\vee, (\Delta_Y^*)^\vee) = (\Delta_Y, \Delta_Y^*)$$

so that a Calabi-Yau hypersurface $\tilde{Z}_g \subset Y$ is a natural mirror of a Calabi-Yau hypersurface $\tilde{Z}_f \subset X$. The point of this proof-of-concept note is to show that this includes a large collection of non-convex polytopes such as those of Hirzebruch $n$-folds.

Finally, we note that through step 3 of Construction 3.1, a choice of an orientation of $\Delta$ induces an orientation of its trans-polar, $\Delta^\vee$.

3.2 An $n = 3$ example: elliptically fibered K3 manifolds

As an illustration, consider the Hirzebruch 3-folds ($m$-twisted $\mathbb{P}^2$-bundles over $\mathbb{P}^1$), specified in Figure 2. The Mori vectors $\ell_a$ give the $U(1)^2$ charges $Q_a^i$ of the GLSM, the analysis of which gives a geometric phase (I), in terms of a K3 hypersurface $f(x) = 0 \subset F_m$. Furthermore, there is the orbifold phase (II) where the combination of Mori vectors $\ell = m\ell_1 + \ell_2 = (0, m, 1, 1)$ specifies the weights of the weighted projective space $\mathbb{P}^3_{(m:m:1:1)}$ to which $F_m$ may be blown down by eliminating the vertex $\nu_1$, augmenting $\Delta^*_{F_m} \rightarrow \text{Conv}(\Delta^*_{F_m}) = \Delta^*_{\mathbb{P}^3_{(m:m:1:1)}}$ and formally setting $x_1 \to 1$. These weights precisely correspond to the charges (3b) for $n = 2$, in which case (5a) defines a K3 surface as the Calabi-Yau hypersurface $\mathbb{P}^3_{(m:m:1:1)}[2(m+1)]$. The quasi-projective space $\mathbb{P}^3_{(m:m:1:1)}$ is singular at $(1, 1, 0, 0)$, and the vector $\nu_1$ corresponds to its MPCP desingularization [21].

The Newton polytope: As seen clearly in Figure 2, the polytope with vertices $\{\nu_1, \ldots, \nu_5\}$ fails to be convex at $\nu_1$ for $m > 2$. The standard definition of its polar, owing to (16), produces the Newton polytope of $\mathbb{P}^3_{(m:m:1:1)}$ rather than that of $F_m$. Furthermore, the Newton polytope of $\mathbb{P}^3_{(m:m:1:1)}$ is depicted by the yellow (shaded) portion of the right-hand side diagram in Figure 3 and has two fractional vertices, $\check{\mu}_1 = (\frac{5}{3}, -1, -1)$ and $\check{\mu}_2 = (1, \frac{5}{3}, -1)$. Its $M$-

\footnote{The “halo” on $\check{\mu}_i$ identifies them as fractional vertices of $(\Delta^*)^{\vee}$.}
integral points correspond through (14) to the monomials
\[
\bigoplus_{k=0}^{8} x_4^{8-k} x_5^k + \bigoplus_{k=0}^{5} (x_2 \oplus x_3) x_4^{5-k} x_5^k + \bigoplus_{k=0}^{2} (x_2^2 \oplus x_2 x_3 \oplus x_3^2) x_4^{2-k} x_5^k,
\]
all generic linear combinations of which fail to be transversal.

To construct the trans-polar of $\Delta_{F_3}^\ast$, we start by noting that the facets $\Phi_1, \cdots, \Phi_6 \subset \Delta^\ast$ are all convex. Following Construction 3.1, we find
\[
\Phi_1^\ast = (-1, -1, -1), \quad \Phi_2^\ast = (-1, -1, 7), \quad \Phi_3^\ast = (2, -1, -2), \quad \Phi_4^\ast = (2, -1, -1), \quad \Phi_5^\ast = (-1, 2, -2), \quad \Phi_6^\ast = (-1, 2, -1).
\]
The vertices $\mu_1, \mu_2$ indeed belong to $(\Delta_{F_3}^\ast)^\circ$, but $\mu_3, \cdots, \mu_6$ lie beyond the fractional vertices of $(\Delta_{F_3}^\ast)^\circ$: they delimit the extension (18), with the quadrangular facet $\Theta_1$ that lies in the $\nu_1^\circ = (x, 1-x, z)$ plane. Since $\nu_1 = [\nu_1, \nu_2] \cap [\nu_1, \nu_3] \cap [\nu_1, \nu_4] \cap [\nu_1, \nu_5]$, $\Theta_1 \subset \nu_1^\circ$ is more precisely delimited by the trans-polar images of the edges adjacent to $\nu_1$:
\[
[\nu_1, \nu_2]^\circ = (-1, 2, z), \quad [\nu_1, \nu_3]^\circ = (2, -1, z), \quad [\nu_1, \nu_4]^\circ = (x, 1-x, -1), \quad [\nu_1, \nu_5]^\circ = (x, 1-x, -2).
\]
With the standard “$\geq -1$” conditions in (15), the computations (22) would have produced an empty set, since the standard polar operation (15) fails to take into account the non-convexity of $\nu_1$. We remedy this by “flipping” the defining inequalities in correlation with (non-)convexity: The extending facet $\Theta_1$ may be defined by first rewriting the $(n, u) \geq -1$ condition in (15) as $(\langle v, u \rangle + 1) \geq 0$, and then flipping the sign of the left-hand side according to the (non-)convexity of $v$:
\[
\text{Here } F = 1 \text{ indicates that the usual condition for the polar ("$\geq -1"\) is reversed—owing to the non-convexity of } \nu_1 \text{ itself; the first two conditions } (F = 2) \text{ are however flipped a second time (and so back to the original inequality) owing to the fact that the edges } [\nu_1, \nu_2] \text{ and } [\nu_1, \nu_3] \text{ are themselves non-convex. In passing, } [\nu_1, \nu_2, \nu_3] \text{ is the sub-polytope of the } \mathbb{P}^2\text{-fiber in } F_m. \text{ Proceeding in this way (step 3 of Construction 3.1) produces the complete Newton polytope } \Delta_{F_3}^\ast \text{ shown to the right in Figure 3. In particular, the facets } \Theta_2, \Theta_3 \text{ are self-crossing, owing to the fact that } \nu_2, \nu_3 \in \Delta_{F_3}^\ast \text{ are each adjacent to three convex and one non-convex edge.}
\]
The spanning polytope $\Delta_{F_3}^\ast$ admits a uniform outward orientation, which then induces an orientation of the Newton polytope $\Delta_{F_3}^\ast$. At each vertex $\nu_\rho \in \Delta_{F_3}^\ast$, this orders the adjacent facets; for example, $\nu_5 = \Phi_5 \cap \Phi_3 \cap \Phi_2$ implies $\Theta_5 = [\mu_5, \mu_3, \mu_2]$, which gives the outward orientation to the “standard part” $[\mu_2, \mu_1, \mu_2]$ of $\Theta_5$, but the inward orientation $[\mu_2, \mu_1, \mu_3, \mu_5]$ within the extension. Similarly, $\nu_3 = \Phi_1 \cap \Phi_2 \cap \Phi_3 \cap \Phi_4$ implies $\Theta_3 = [\mu_1, \mu_2, \mu_3, \mu_4]$, giving the outward orientation to “standard part” $[\mu_1, \mu_1, \mu_2]$ of $\Theta_3$, but the inward orientation $[\mu_4, \mu_3, \mu_1]$ within the extension. In a similar fashion, this gives the facets $\Theta_{4, 5}$ and $\Theta_1$ the

\text{Duality relations preserve (reverse) orientations in even (odd) dimensions.}
\[ \mu_i := \Phi_i^\top := \{ m : \langle m, \nu \rangle = -1, \; \nu \in \Phi_i \} \]

\[ \Theta_\rho := \nu_\rho^\top := \{ m : \langle m, \nu_\rho \rangle = -1 \} \]

If \([\nu_\rho, \nu_\rho'] = \Phi_i \cap \Phi_j\),
then \(\Theta_\rho \cap \Theta_{\rho'} = [\mu_j, \mu_i]\)

If \(\nu_\rho = \Phi_i \cap \cdots \cap \Phi_k\),
then \(\Theta_\rho = [\mu_k, \cdots, \mu_i]\)

\[ \Delta_{F_3}^* := (\Delta_{F_3}^*{\top}) \]

\[ \Theta_3 = [\mu_4, \mu_3, \mu_2, \mu_1] \]
\[ \Theta_5 = [\mu_2, \mu_3, \mu_5] \]
\[ \Theta_1 = [\mu_3, \mu_4, \mu_6, \mu_5] \]

Figure 3: The spanning polytope \(\Delta_{F_3}^*\) and the Newton polytope \(\Delta_{F_3}\) with several polar pairs of elements indicated. The outward orientation of \(\Delta_{F_3}^*\) at a vertex \(\nu_\rho\) orders the adjacent facets \(\Phi_i \cap \cdots \cap \Phi_k\), and so induces the (reverse) ordering of \(\Phi_i^\top\), and the compatible orientation for \(\Theta_\rho\).
outward and opposite inward orientations, respectively. This orientation will be essential in the combinatorial formulae for the Euler and Hodge numbers, see section 4 and Appendix B.

Finally, the standard formula (14) associates the Laurent monomials

\[
\begin{align*}
[\mu_4, \mu_6] & : \bigoplus_{k=0}^{3} x_2^{3-k} x_3^k x_4, & [\mu_3, \mu_5] & : \bigoplus_{k=0}^{3} x_2^{3-k} x_3^k x_5.
\end{align*}
\]

(24)

Straightforward computation shows that generic Laurent polynomials formed with both (20) and (24) are transversal: following the GLSM analysis in Section 2, the polynomial \( f(x) \) and its gradient \( \partial f(x)/\partial x_i \) vanish simultaneously only in the Landau-Ginzburg orbifold phase, where \( x_2, x_3, x_4, x_5 \to 0 \).

4 Combinatorial calculations

Let us first consider Batyrev’s Euler characteristic formula [21, 29]

\[
\chi(\hat{Z}_f) = \sum_{k=1}^{\dim X - 2} (-1)^{k-1} \sum_{\theta \subset \Delta_X} d(\theta) d(\theta^*)
\]

(25)

where \( \hat{Z}_f \) is the MPCP desingularization of the anticanonical \( \Delta_X \)-regular (transversal) hypersurface \( f(x) = 0 \) in a toric variety \( X \) and \( \Delta_X \) is its Newton polytope. For every face \( \theta \subset \Delta_X \) in the Newton polytope, \( \theta^* \subset \Delta^*_X \) is the dual face\(^{13}\) in the spanning polytope such that \( \dim(\theta) + \dim(\theta^*) = \dim(\hat{Z}_f) \). In fact, there is a natural generalization of (25) in which we sum over all the codimension \( k \) faces,

\[
\chi(\hat{Z}_f) = \sum_{k=-1}^{\dim X} (-1)^{k-1} \sum_{\theta \subset \Delta_X} d(\theta) d(\theta^*)
\]

(26)

where for \( \dim(\theta) = -1 \), \( \theta \) is the unique interior point in \( \Delta_X \) and \( \theta^* = \Delta^*_X \), and similarly for \( \dim(\theta) = \dim X \), where \( \theta = \Delta_X \) and so \( \theta^* \) is the unique interior point in \( \Delta^*_X \). Furthermore, because we restrict to star-triangulations, it follows that

\[
\begin{align*}
d(\Delta^*_X) &= \sum_{\dim(\theta) = 0} d(\theta) d(\theta^*), & d(\Delta_X) &= \sum_{\dim(\theta) = \dim X - 1} d(\theta) d(\theta^*)
\end{align*}
\]

(27)

since \( \dim(\theta^*) = \dim X - 1 \) and \( \dim(\theta^*) = 0 \) and hence the two sums range over codimension-one faces in \( \Delta \) and \( \Delta^* \), respectively. Thus, the contribution from \( k = -1 \) and \( k = 0 \) cancel, as do the \( k = \dim X - 1 \) and \( k = \dim X \) terms.

We now will demonstrate that the trans-polar pair of polytopes \( (\Delta^*_X, \Delta_X := (\Delta^*_X)^\circ) \) provides for computing the basic topological characteristics — and that the orientations discussed between (20) and (24) turn out to be crucial. In light of this, we propose the following conjecture generalizing Batyrev’s construction \([21, 29]\)\(^{14}\):

\(^{13}\)For faces of all nonzero codimension, the dual of a face (as used here) is the trans-polar of that face and \( \dim(\theta) + \dim(\theta^*) = n - 1 \). On the other hand, the dual of the entire polytope \( (\text{codim} = 0) \) is not the trans-polar polytope (which has the same rather than the complementary dimension) but the unique integral point (the origin) that is internal to the entire trans-polar polytope.

\(^{14}\)The toric construction of mirror pairs of Calabi-Yau manifolds restricted to Fermat hypersurfaces in weighted projective space was first observed by Roan [30].
Conjecture 4.1. The Euler number, $\chi(\hat{Z}_f)$, and Hodge numbers, $h^{1,1}(\hat{Z}_f)$ and $h^{n-2,1}(\hat{Z}_f)$ for a Calabi-Yau $(n-1)$-fold $\hat{Z}_f$, which is the MPCM desingularization of the anticanonical $\Delta_X$-regular (transversal) hypersurface $f(x) = 0$ in a toric variety $X$ with $\Delta_X$ its VEX Newton polytope, are given by (25),

$$h^{n-2,1}(\hat{Z}_f) = l(\Delta_X) - 5 - \sum_{\text{codim } \theta = 1} l^*(\theta) + \sum_{\text{codim } \theta = 2} l^*(\theta) \cdot l^*(\theta^*),$$

and

$$h^{1,1}(\hat{Z}_f) = l(\Delta_X) - 5 - \sum_{\text{codim } \theta^* = 1} l^*(\theta^*) + \sum_{\text{codim } \theta^* = 2} l^*(\theta^*) \cdot l^*(\theta),$$

respectively, where $l(\theta)$ ($l(\theta^*)$) is the number of internal points in the face $\theta \subset \Delta_X$ ($\theta^* \subset \Delta_X^*$), which may be negative if $\theta$ ($\theta^*$) has opposite orientation. The similarly constructed Calabi-Yau $(n-1)$-fold $\hat{Z}_g$, which is the MPCM desingularization of the anticanonical $\Delta_Y$-regular (transversal) hypersurface $g(y) = 0$ in a toric variety $Y$ with $\Delta_Y = \Delta_X^*$ its VEX Newton polytope, is the mirror manifold to $\hat{Z}_f$, with the roles of $\Delta_X$ and $\Delta_X^*$ interchanged, such that $h^{1,1}(\hat{Z}_g) = h^{n-2,1}(\hat{Z}_f)$ and $h^{n-2,1}(\hat{Z}_g) = h^{1,1}(\hat{Z}_g)$, and thus $\chi(\hat{Z}_g) = (-1)^{n-1} \chi(\hat{Z}_f)$.

We first focus on the example $K3 \subset \mathcal{F}_3$ from Section 3.2, followed by the corresponding Calabi-Yau threefolds, where we also calculate $h^{1,1}$ and $h^{2,1}$; additional examples may be found in the companion paper [23].

4.1 K3

Adapting (25) to the case of the $K3$, $\hat{Z}_f$ hypersurface $f(x) = 0 \subset \mathcal{F}_m$, the indicated summation should extend only over 1-dimensional faces (edges) $\theta \subset \Delta_{\mathcal{F}_m}$ in the Newton polytope (the dual of which, $\theta^* \subset \Delta_{\mathcal{F}_m}^*$, are edges in the spanning polytope):

$$\chi(\hat{Z}_f) = \sum_{\text{dim } \theta = 1}^{\text{dim } \theta} d(\theta) d(\theta^*).$$

All edges $\theta^* \subset \Delta_{\mathcal{F}_m}^*$ have unit degree for $m \neq 2$, in which case the sum reduces to the degrees of the edges in the Newton polytope $\Delta_{\mathcal{F}_m} = (\Delta_{\mathcal{F}_m}^*)^\vee$. The $m \leq 2$ cases are well understood and convex so that the trans-polar operation reduces to the familiar polar (15). We then focus on $m \geq 3$.

As is evident from Figure 3 and 6 below, $\Delta_{\mathcal{F}_m}$ has a total of nine edges:

- the one tallest vertical edge $[\nu_2, \nu_3]^\vee = \Theta_2 \cap \Theta_3 = [\mu_1, \mu_2]$ has degree $2 + 2m$;
- two horizontal edges: $[\nu_2, \nu_4]^\vee = \Theta_2 \cap \Theta_4 = [\mu_1, \mu_6]$ and $[\nu_3, \nu_4]^\vee = \Theta_3 \cap \Theta_4 = [\mu_1, \mu_4]$, both of which have degree 3;
- two slanted edges: $[\nu_2, \nu_5]^\vee = \Theta_2 \cap \Theta_5 = [\mu_2, \mu_5]$ and $[\nu_3, \nu_5]^\vee = \Theta_3 \cap \Theta_5 = [\mu_2, \mu_3]$, both of which have degree 3;
- two horizontal edges in the extension: $[\nu_1, \nu_4]^\vee = \Theta_1 \cap \Theta_4 = [\mu_4, \mu_6]$ and $[\nu_1, \nu_5]^\vee = \Theta_1 \cap \Theta_5 = [\mu_3, \mu_5]$, both of which have degree 3;
- two vertical edges in the extension: $[\nu_1, \nu_2]^\vee = \Theta_1 \cap \Theta_2 = [\mu_5, \mu_6]$ and $[\nu_1, \nu_3]^\vee = \Theta_1 \cap \Theta_3 = [\mu_3, \mu_4]$, both of which have degree $-(m-2)$: a quick comparison with the $m \leq 2$ cases (see Figure 6) shows that for $m \geq 3$ these two edges manifestly extend in the direction opposite from the $m \leq 2$ cases.

14
Tallying these contributions produces in (30):

\[
\chi(\hat{Z}_f) = (2+2m) + 2(3) + 2(3) + 2(3) + 2[-(m-2)] = 24, \quad m \geq 3. \tag{31}
\]

In fact, the computation is also true for \(m = 2\); not only is the end result independent of \(m\), but the method itself extends.

Finally, note that since (30) is completely symmetric in exchanging \(\theta\) and \(\theta^*\), it is clear that the mirror \(K3, \hat{Z}_g\), to the hypersurface \(f(x) = 0 \subset \mathcal{F}_m\), is defined as a hypersurface \(g(y) = 0\) in the toric variety \(Y\) constructed by exchanging the roles of \(\Delta^*\) and \(\Delta\).

### 4.2 Calabi-Yau three-folds

For illustration, consider the Calabi-Yau 3-fold \(\hat{Z}_f\) hypersurfaces \(f(x) = 0\) in the Hirzebruch 4-folds \(F_4\) \((m\)-twisted \(\mathbb{P}^3\)-bundles over \(\mathbb{P}^1\))^15, where in analogy with \(K3\), \((x_1, \ldots, x_4)\) and \((x_5, x_6)\) are the homogeneous fiber and base coordinates for the \(\mathbb{P}^3\) and \(\mathbb{P}^1\), respectively.

\[
\begin{array}{lllllllllllll}
\Delta^*_{\mathbb{F}_m} & \nu_0 & \nu_1 & \nu_2 & \nu_3 & \nu_4 & \nu_5 & \nu_6 \\
\hline
\text{fiber} & 0 & -1 & 1 & 0 & 0 & 0 & -m \\
\text{base} & 0 & -1 & 0 & 0 & 1 & 0 & -m \\
\end{array}
\]

\[\mathcal{M}(\Delta^*_{\mathbb{F}_m}) = \begin{cases} 
\ell_1 = -4 & 1 & 1 & 1 & 0 & 0 \\
\ell_2 = m-2 & -m & 0 & 0 & 0 & 1 & 1 \\
x_0 & x_1 & x_2 & x_3 & x_4 & x_5 & x_6 
\end{cases}\]

For \(n = 4\), the extension in the Newton polytope, \((\nu_1)\), is delimited by \([\nu_1, \nu_2]^{\mathbb{V}}, [\nu_1, \nu_3]^{\mathbb{V}}, [\nu_1, \nu_4]^{\mathbb{V}}, [\nu_1, \nu_5]^{\mathbb{V}}\) and \([\nu_1, \nu_6]^{\mathbb{V}}\), and so is the region defined by:

\[
u \in M_\mathbb{R} : \langle \nu_1, u \rangle = -1 \quad \& \quad \begin{cases}
(-1)^F(\nu_2, u + 1) \geq 0, & F = 2; \\
(-1)^F(\nu_3, u + 1) \geq 0, & F = 2; \\
(-1)^F(\nu_4, u + 1) \geq 0, & F = 2; \\
(-1)^F(\nu_5, u + 1) \geq 0, & F = 1; \\
(-1)^F(\nu_6, u + 1) \geq 0, & F = 1.
\end{cases} \tag{33}
\]

Here \(F = 1\) indicates that the usual condition for the polar (“\(\geq -1\)”) is reversed—again owing to the non-convexity of \(\nu_1\); the first three conditions (\(F = 2\)) are however flipped a second time (and so equal the original inequality) as the vertices \([\nu_1, \nu_2, \nu_3, \nu_4]\) form the sub-polytope of the \(\mathbb{P}^3\)-fiber in \(F_m\); the 2-faces \([\nu_1, \nu_i, \nu_j]\) of this sub-polytope are non-convex in \(\Delta^*_{\mathbb{F}_m}\) for \(m \geq 3\). In turn, \(\nu_4\) and \(\nu_5\) span the sub-polytope of the base \(\mathbb{P}^1\).

The extension in the Newton polytope thus takes the form of a 3-sided prism,

\[
\{(x, y, 1-x-y, z), \quad -1 \leq x \leq 3, \quad -1 \leq y \leq (2-x), \quad (1-m) \leq z \leq -1 \}, \tag{34}
\]

generalizing the rectangle for \(n = 3\) and vertical edge for \(n = 2\). The vertical edge remains the same for general \(n\) while the base of the extension is an \((n-2)\)-dimensional simplex.

---

^15The Hirzebruch 4-fold \(F_4\) may also be described as a generic degree-(1, \(m\)) hypersurface in \(\mathbb{P}^4 \times \mathbb{P}^1\), in which the Calabi-Yau hypersurfaces have \(h^{1,1} = 2, h^{2,1} = 86, \) triple intersection numbers \(\kappa_{1,1,1} = 2+3m\) \(\kappa_{1,2,2} = 4\) and \(\kappa_{2,2,2} = 0 = \kappa_{2,2,2}\) and the second Chern class evaluations \(c_2[J_1] = 44+6m\) and \(c_2[J_2] = 24\) [5]. Then, the integral basis change \((J_1, J_2) \rightarrow (J_1+cJ_2, J_2)\) identifies \(F_4 \overset{\sim}{\rightarrow} F_{m+4c}\) as diffeomorphic [31]. We verify that the toric specification (32) reproduces this (classical) topological data completely.
The Euler characteristic: We first calculate the Euler number along the lines of the K3 in the previous subsection, evaluating the two terms in Batyrev’s expression (25) for an \((n = 4)\)-dimensional ambient toric variety (see also [21, Theorem 4.5.3]):

\[
\chi(\hat{Z}_f) = \sum_{\dim \theta = 1} d(\theta) d(\theta^*) - \sum_{\dim \theta = 2} d(\theta) d(\theta^*),
\]

(35)

Here \(\theta \subset \Delta_{F_m}\) are faces in the (extended) Newton polyhedron for \(F_m\): \(\theta^* \subset \Delta_{F_m}^\ast\) are their trans-polar faces in the spanning polytope. Since now \(\dim(\theta) + \dim(\theta^*) = \dim(\hat{Z}_f) = 3\), edges in the Newton polytope are paired with 2-faces in the spanning polytope and vice versa.

We refer the reader to the Appendix B for the details of the calculation. It suffices to say that in analogy with the \(n = 3\) case of K3, there are in the extension of \(\Delta_{F_m}\) three 1-faces \(\theta\), i.e., edges in \(\Delta_{F_m}\), for which \(d(\theta) = -1\) and also three 2-faces \(\theta\), i.e., edges in \(\Delta_{F_m}\), for which \(d(\theta) = -8\). In the latter, two of the four boundary 1-faces have \(d(\theta) = -1\), while the other two have \(d(\theta) = 4\). The result: \(\chi = 56 - 224 = -168\), in agreement with the gCICY result [1, 5].

The Hodge numbers: We next turn to calculating the Hodge numbers \(h^{2,1}\) and \(h^{1,1}\) following Batyrev’s formulae [21, Theorem 4.3.7]:

\[
h^{2,1}(Y_m) = l(\Delta_{F_m}) - 5 - \sum_{\codim \theta = 1 \atop \theta \subset \Delta_{F_m}^\ast} l^*(\theta) + \sum_{\codim \theta = 2 \atop \theta \subset \Delta_{F_m}^\ast} l^*(\theta) \cdot l^*(\theta^*),
\]

(36)

and [21, Theorem 4.4.2]:

\[
h^{1,1}(Y_m) = l(\Delta_{F_m}^\ast) - 5 - \sum_{\codim \theta^* = 1 \atop \Phi \subset \Delta_{F_m}^\ast} l^*(\theta^*) + \sum_{\codim \theta^* = 2 \atop \Phi \subset \Delta_{F_m}^\ast} l^*(\theta^*) \cdot l^*(\theta).
\]

(37)

Here, \(\theta^* \subset \Delta_{F_m}^\ast\) is the facet dual to \(\theta \subset \Delta_{F_m}\), and vice versa. To avoid the ambiguity of counting internal points in negative-degree faces, we rewrite \(l^*(\theta)\) and \(l^*(\theta^*)\) using the general formulae (51) and (49) to re-express the summands in terms of various \(k\)-face degrees. Thus, Batyrev’s formulae (37) and (36) take the following form:

\[
h^{2,1} = \sum_{\dim \theta = 1} d(\theta) + \sum_{\dim \theta^* = 1} d(\theta^*) - 4 + N_0 - N_1 + \frac{1}{2} \sum_{\dim \theta = 2} (d(\theta) - c(\theta)) d(\theta^*),
\]

(38)

\[
h^{1,1} = \sum_{\dim \theta^* = 1} d(\theta^*) + \sum_{\dim \theta = 1} d(\theta) - 4 + N_0^* - N_1^* + \frac{1}{2} \sum_{\dim \theta^* = 2} (d(\theta^*) - c(\theta^*)) d(\theta),
\]

(39)

where \(N_k\) (\(N_k^*\)) refers to the number of \(k\)-faces in \(\Delta_{F_m}\) (\(\Delta_{F_m}^\ast\)) and \(c(\theta(2))\) is the effective circumference of \(\theta(2)\), see (51). The reader can consult Appendix B.2 for the details of the calculation the result of which is that \(h^{2,1} = 86\) and \(h^{1,1} = 2\), independent of \(m\) and as with the Euler number in agreement with the gCICY result [1, 5].

4.3 Mirror models

As mentioned above (19), the trans-polar pair of polytopes \((\Delta_{F_m}, \Delta_{F_m}^\ast)\) defines a pair of toric varieties, \((F_m, F_m^\ast)\), in which the (MPCP-desingularized) Calabi-Yau hypersurfaces are natural mirrors [21, 28]. In particular, the above explicit computations of the Euler and Hodge numbers verifies that swapping \(\Delta_{F_m} \leftrightarrow \Delta_{F_m}^\ast\) indeed has the expected mirror effect. We now explore this relationship further and provide additional corroboration to this relationship.
For concreteness, consider the trans-polar pair of polytopes \((\Delta_{F_3}, \Delta_{F_3}^\ast)\), see Figure 3. Expressed in terms of the homogeneous coordinates associated with the vertices of \(\Delta_{F_3}^\ast\), we choose a minimal set of vertices of \(\Delta_{F_3}\) that will generate the \(M\)-lattice\footnote{Restricting the standard part of the Newton polytope to \(M\)-integral points results in a drastic example of non-transversality: the origin is no longer internal but “surfaces” into the “cut-off” facet outlined in Figure 3. Since our inclusion of the “extension” (i.e., Laurent polynomials) restores transversality even in this drastic case, there most certainly exist much milder cases, where analogous “extensions” in the Newton polytope (and Laurent monomials) restore transversality.} [22]. That is, for the example of \(F_3\), we select \(\mu_1, \mu_2, \mu_3, \mu_5\) and obtain:

\[
\begin{align}
  f_{\min}(F_3) &= a_1 x_5^8 + a_2 x_4^8 + a_3 \frac{x_2^3}{x_4} + a_5 \frac{x_3^3}{x_4} 
  &\in \mathbb{P}^3_{(3:3:1:1)}[8], \quad (40a) \\
  g_{\min}(F_3^\gamma) &= b_2 y_3^3 + b_3 y_5^3 + b_4 \frac{y_2^8}{y_3 y_5} + b_5 y_1^8 
  &\in \mathbb{P}^3_{(3:5:8:8)}[24], \quad (40b)
\end{align}
\]

where the monomials in \((40b)\) correspond to the vertices \(\nu_i\) of the complex hull of \(\Delta_{F_3}^\ast\), which analogously generate the \(N\) lattice\footnote{We note that there are two triangulations of the above minimal set of \(\nu_i\) giving rise to two phases in the enlarged Kähler moduli space corresponding to \(i\) the orbifold phase of the hypersurface in the unresolved weighted projective space, and \(ii\) the Landau-Ginzburg orbifold, and similarly for the mirror geometry in terms of the \(\mu_i\).}. Straightforward computation along the lines of Appendix A shows that the generic polynomials \((40)\) are transversal, due to the Laurent monomials, and the polynomials in each pair are each other’s transpose:

\[
\text{(40a) \& (40b) } \Rightarrow \quad M_f(F_3) = \begin{bmatrix} 0 & 0 & 0 & 8 \\ 0 & 0 & 8 & 0 \\ 3 & 0 & -1 & 0 \\ 0 & 3 & -1 & 0 \end{bmatrix} = M_f^\gamma(F_3^\gamma). \quad (41)
\]

Following the prescription of Ref. [20], the maximal phase symmetry of \((40a)\) is \(\mathbb{Z}_3 \times \mathbb{Z}_8 \times \mathbb{Z}_{24}\), generated by \(\gamma_1 := (\mathbb{Z}_3; \frac{1}{3}; \frac{2}{8}; 0, 0)\), \(\gamma_2 := (\mathbb{Z}_8; 0, 0, 0, \frac{1}{5})\) and \(\gamma_3 := (\mathbb{Z}_{24}; \frac{1}{24}; \frac{1}{22}; \frac{1}{5}, 0)\). Then, \(9(\gamma_2 + \gamma_3) = (\mathbb{Z}_8; \frac{3}{8}; \frac{3}{8}; \frac{1}{8})\) generates the “quantum symmetry,” the discrete subgroup of the \(\mathbb{P}^3_{(3:3:1:1)}\) projectivization, leaving a \(\mathbb{Z}_3 \times \mathbb{Z}_{24}\) geometric symmetry generated for example as:

\[
\begin{bmatrix} x_2 \\ x_3 \\ x_4 \\ x_5 \end{bmatrix} : \begin{cases} \mathbb{G} = \mathbb{Z}_3 \times \mathbb{Z}_{24}, \\ \mathbb{Q} = \mathbb{Z}_8. \end{cases}
\]

Analogously, the maximal phase symmetry of \((40b)\) is also \(\mathbb{Z}_3 \times \mathbb{Z}_8 \times \mathbb{Z}_{24}\), generated by \(\gamma_1^\gamma := (\mathbb{Z}_3; 0, 0, \frac{1}{3}, \frac{2}{3})\), \(\gamma_2^\gamma := (\mathbb{Z}_8; \frac{3}{8}, 0, 0, 0)\) and \(\gamma_3^\gamma := (\mathbb{Z}_{24}; 0, \frac{1}{24}, \frac{2}{3}, \frac{2}{3})\). Then, \(\gamma_2^\gamma + 5\gamma_3^\gamma = (\mathbb{Z}_{24}; \frac{1}{8}, \frac{5}{24}, \frac{1}{3}, \frac{1}{3})\) generates the “quantum symmetry,” the discrete subgroup of the \(\mathbb{P}^3_{(3:5:8:8)}\) projectivization, leaving a \(\mathbb{Z}_3 \times \mathbb{Z}_8\) geometric symmetry generated for example as:

\[
\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_5 \end{bmatrix} : \begin{cases} \mathbb{G}^\gamma = \mathbb{Z}_3 \times \mathbb{Z}_8, \\ \mathbb{Q}^\gamma = \mathbb{Z}_{24}. \end{cases}
\]

To swap the geometric and quantum symmetry, we should consider \((42), (43)/\mathbb{Z}_3\) for a mirror pair of Landau-Ginzburg orbifold models, using the indicated \(\mathbb{Z}_3\)-action. In particular, upon this \(\mathbb{Z}_3\)-quotient, \(\mathbb{G}^\gamma = \mathbb{Z}_8\) and \(\mathbb{Q}^\gamma = \mathbb{Z}_3 \times \mathbb{Z}_{24}\).
We note that the ratio of the sizes of the geometric and the quantum symmetry groups equals the ratio of the degrees of the polytopes\(^{18}\):

\[
\frac{|Q^\triangledown|}{|G^\triangledown|} = \frac{|G|}{|Q|} = \frac{324}{8} = 9 = \frac{d(\Delta_{F_3})}{d(\Delta^*_F)} = \frac{54}{6} = \frac{d(\Delta^*_{F_3})}{d(\Delta_{F_3})}. \tag{44}
\]

The analogous relationship persists also for any \(n \geq 2\), and for \(m \geq 0\). Given our choice of vertices and monomials \((40)\), this chain of equalities is in complete agreement with the detailed analysis in Section 3 of Ref. [22]. The fact that these relationships continue to hold also for the \(n = 2, 3, 4\) and \(m \geq 0\) sequences of Laurent polynomials such as \((40)\) we find to provide additional corroboration of our extension of toric methods in Section 3 and their application in Section 4, and of Construction 3.1 and Conjecture 4.1 in particular.

We close by noting that even without a detailed analysis of the Landau-Ginzburg orbifolds or the more complete mirror pair of GLSM’s, the discrete symmetries are essential both in constructing the Hilbert spaces of the Landau-Ginzburg models and in significantly restricting the Yukawa couplings via the Wigner-Eckart theorem. In fact, the symmetries of the defining (Laurent) polynomials \(f(x)\) and \(g(y)\) will play such an important role in all phases of the corresponding GLSM’s. We find it therefore significant that the phase symmetries fully conform to the transposition prescription \([20, 22]\).

5 Conclusions and Outlook

In this paper we have found that there is a natural generalization of the GLSM to Laurent superpotentials in which the phase-diagram of the enlarged Kähler moduli space, i.e., the secondary fan is constructed from the triangulations of the spanning polytope \(\Delta_X^\triangledown\) (and its convex hull) of non-Fano toric varieties. Our construction 3.1 specifies the “trans-polar” operation, which extends the standard “polar” operation so as to apply to all VEX polytopes, including the above \(\Delta_X^\triangledown\) and the Newton polyhedron \(\Delta_X := (\Delta_X^\triangledown)^\triangledown\), as well as the original class of reflexive polytopes considered by Batyrev \([21]\).

In particular, for polytopes corresponding to the Hirzebruch \(n\)-folds \([5]\) \(\mathcal{F}_m^{(n)}\) for \(m \geq 0\) (collectively denoted in the subsequent listing as \(X\)), we have also shown that the spanning polytope \(\Delta_X^\triangledown\) and the Newton polytope \(\Delta_X := (\Delta_X^\triangledown)^\triangledown\) admit a mutually compatible orientation. The orientation provides a sign for every face in each polytope and each cone in the fan that it spans. Furthermore, \(\Delta_X^\triangledown\) and \(\Delta_X\) both admit oriented star-triangulations (compatible with the orientation of the polytopes), which provides a sign to the degree of every star-simplex. Allowing the degree of a star-simplex to be negative is crucial for correctly calculating the Euler and Hodge numbers from the combinatorial data in the pair of oriented polytopes \((\Delta_X^\triangledown, \Delta_X)\) and their oriented star-triangulations by adapting and generalizing Batyrev’s formula \((25)\). Note that the extension, \(\text{xtn}(\Delta_X)\), \((18)\) within the (complete) Newton polytope \(\Delta_X\) is essential not only for the computation of the above topological data, but also in that the Laurent monomials corresponding to the integral points of \(\text{xtn}(\Delta_X)\) render the generic anticanonical polynomial transversal (“\(\Delta_X\)-regular” \([21]\)). Finally, as \(\Delta_X^\triangledown\) spans the fan of \(X\), \(\Delta_X^\triangledown := \Delta_X\) defines a trans-polar toric \(n\)-fold \(X^\triangledown\), the fan of which is

\(^{18}\)Here the orders of the geometric and quantum symmetries are also computed by considering mirror interpretation of the \(\mu_i\), as edges \(\bar{\mu}_i = (\mu_i, 1)\) spanning a cone in \(\bar{M} = M \oplus \mathbb{Z}\) describing the mirror geometry (and similarly for the \(\nu_j\), with \(\bar{\nu}_j = (\nu_j, 1)\) of a cone in \(\bar{N} = N \oplus \mathbb{Z}\)). The linearly independent \(\bar{\mu}_i\) form a \(4 \times 4\) matrix with determinant 72, describing the mirror toric ambient space as a discrete quotient of \(\mathbb{C}^4\) of order \(|G| = 72\). Similarly, the original toric variety is a \(Q = \mathbb{Z}_n\) quotient of \(\mathbb{C}^4\) since \(\bar{\nu}_i\) form a \(4 \times 4\) matrix with determinant 8 \([32]\).
spanned by $\Delta_X$. Hence, swapping $\Delta^*_X \leftrightarrow \Delta^*_X$ evidently induces the expected mirror effect on the Euler and Hodge numbers. This indicates the pair of (MPCP desingularized) anti-canonical hypersurfaces in the toric varieties specified by the trans-polar pair of polytopes $(\Delta^*_X, \Delta_X := \Delta^*_X)$ as prime candidates for mirror manifolds. Further evidence of mirror symmetry also follows from the exchange of “geometric” and “quantum” phase symmetries [20] for the Landau-Ginzburg orbifold phases obtained from a minimal choice of superpotentials, $f_{\text{min}}(X)$ and $g_{\text{min}}(Y)$, related by transposition of the matrix of exponents of anti-canonical monomials.

The present work has two natural extensions. First, it would be desirable to put the results presented herein on a rigorous mathematical footing, and in particular provide a proof of our main Conjecture 4.1, including to what extent it is valid. Second, and the main motivation of the program at hand, is to understand the enlarged Kähler moduli space in order to calculate the non-perturbative corrections, i.e., Gromow-Witten invariants. This would allow us to determine whether the observed (mod $n$) symmetry within the class of Calabi-Yau hypersurfaces in the Hirzebruch $n$-folds is indeed broken.

Acknowledgements

We would like to thank Lara Anderson, Andreas Braun, Charles Doran, James Gray, Kevin Iga and Djordje Minić for helpful discussions on the topics in this article. A Transversality of $f(x)$

This is easily seen for $m = 1, 2$, when $f(x)$ is a regular polynomial. That this also holds for $m > 2$, consider the case where $m = 3, n = 2$:

\begin{align}
\quad f(x) &= a_{21} \frac{x_2^2}{x_3} + a_{22} \frac{x_2^2}{x_4} + b_1 x_1^2 x_3^5 + b_2 x_1^2 x_4^5; \\
\partial_1 f(x) &= 2 x_1 (b_1 x_3^5 + b_2 x_4^5), \quad \partial_2 f(x) = 2 a_{21} \frac{x_2}{x_3} + 2 a_{22} \frac{x_2}{x_4}, \\
\partial_3 f(x) &= 5 b_1 x_1^2 x_3^4 - a_{21} \frac{x_2^2}{x_3^2}, \quad \partial_4 f(x) = 5 b_2 x_1^2 x_4^4 - a_{22} \frac{x_2^2}{x_4^2}.
\end{align}

The base-locus of this system is $(0, 0, x_3, x_4) \cup (x_1, 0, 0, 0)$: The expressions (45) vanish simultaneously in the two multi-limits identified in Table 1:

1. $x_1, x_2 \rightarrow 0$, and with $(x_3, x_4)$ free; this is phase IV, including its boundaries $i$ and $iv.$
2. $x_2, x_3, x_4 \to 0$, provided (45c) are solved by setting $x_3 = \alpha^{3/2} x_1$ and $x_4 = \beta^{3/2} x_1$ with 
$\alpha^6 = \frac{241}{561}$ and $\beta^6 = \frac{222}{562}$, whereupon the $x_2 \to 0$ may be taken requiring only that $x_2 < x_1$ 
but leaving $x_1$ otherwise free; this is phase III including its boundaries $iii$ and $iv$.

Including other monomials from the Newton polytope makes the system more generic, and is 
on general grounds expected not to worsen the above behavior.

Note that the GLSM analysis in Section 2 is more detailed as it catalogues the branches 
of the base-locus of the superpotential $x_0 : f(x)$, not just $f(x)$.

B Combinatorial Calculations

B.1 K3

Adapting again Batyrev’s $n \geq 4$ formula [21, 29], we write:

\[ h^{1,1} = [l(\Delta_{F_m}^*) - 4 - \sum_{\text{codim} (\theta) = 2 \atop \theta \subset \Delta_{F_m}} l^*(\theta)] + [l(\Delta_{F_m}) - 4 - \sum_{\text{codim} (\theta) = 1 \atop \theta \subset \Delta_{F_m}} l^*(\theta)] + \sum_{\text{codim} (\theta) = 1 \atop \theta \subset \Delta_{F_m}} l^*(\theta) l^*(\theta^*) , \] (46)

where the first part is the contribution from the Picard group, the second counts the “toric” 
deformations of the complex structure, and the final term is a correction term which can 
be thought of as counting either non-polynomial deformations of the complex structure or 
non-toric Kähler deformations.

We now address these terms in turn.

Picard term: It should be manifest from Figure 3 that $^{19}$

\[ l(\Delta_{F_m}^*) = 6 \quad \text{and} \quad l^*(\Phi_i) = 0 \quad \text{for all} \quad \Phi_i \subset \Delta_{F_m}^* \] (47)

independently of $m$: the constellation of $\nu_1, \nu_2, \nu_3, \nu_4$ remains fixed for all $m \geq 0$, and only $\nu_5 = (-m, -m, -1)$ is moved further and further into the 7th octant. However, as $m$ grows, 
neither the facets $\Phi_2, \Phi_3, \Phi_5$ nor the edges $[\nu_2, \nu_5], [\nu_3, \nu_5], [\nu_1, \nu_5]$ acquire any internal points. Therefore,

\[ [l(\Delta_{F_m}^*) - 4 - \sum_{i=1}^{6} l^*(\Phi_i)] = [6 - 4 - 6 \cdot (0)] = 2. \] (48)

This result perfectly agrees with the homology algebra computation: $H^2(F_m, \mathbb{Z})$ is indeed 
2-dimensional, generated by the Kähler forms of $\mathbb{P}^3 \times \mathbb{P}^1$ when realizing $F_m$ as a degree-(1, $m$) 
hypersurface in $\mathbb{P}^3 \times \mathbb{P}^1$, and both generators are for all $m \geq 0$ inherited by the Calabi-Yau 
hypersurface $K3 \subset F_m$ [5].

Toric deformations: In order to calculate the second (and third) term in (46) it is necessary 
to understand the contribution of the extension part of the Newton polytope $\Delta_{F_m}$ and how 
it varies with $m$. In particular we need to understand how to count the effective number of integral points interior to the various codimension one and two faces. Since $\Theta_1$ and portions 
of $\Theta_2$ and $\Theta_3$ are negatively oriented (see Section 3.2), this will require some care.

We find it expedient to relate the number of points in the relative interior of a face to the degree 
of that face:

$^{19}$The fact that $l(\Delta_{F_m}^*) = \chi(F_m)$ generalizes Corollary 7.3 in [29] to our class of non-Fano toric varieties 
constructed in terms of the non-reflexive $\Delta_{F_m}^*$, as well as to arbitrary dimension $n$ of the ambient toric variety.
0-dim.: \(d(\theta^{(0)}) = 0! \cdot \text{Vol}_0(\theta^{(0)}) = 1\) for \(\theta^{(0)}\) a vertex.

1-dim.: \(d(\theta^{(1)}) = 1! \cdot \text{Vol}_1(\theta^{(1)})\) for an edge \(\theta^{(1)}\) of length \(\text{Vol}_1(\theta^{(1)})\). Since every edge has two end-points, and is subdivided by its \(l^*(\theta^{(1)})\) interior points into \(l^*(\theta^{(1)}) + 1\) unit-length 1-simplices, it follows that

\[ l^*(\theta^{(1)}) = d(\theta^{(1)}) - 1. \tag{49} \]

Note that a negatively oriented edge of (signed) length \(-\ell\) (formally) therefore has \(-\ell + 1\) points in its relative interior; a negatively oriented unit-size edge (formally) has \(-2\) points in its relative interior.

2-dim.: \(d(\theta^{(2)}) = 2! \cdot \text{Vol}_2(\theta^{(2)})\) for a 2-face \(\theta^{(2)}\) of area \(\text{Vol}_2(\theta^{(2)})\). Let \(\theta^{(2)}\) denote a 2-face that has \(l^*(\theta^{(2)})\) (integral) points in its relative interior, \(N\) vertices \(\theta^{(0)}\) (and so also \(N\) edges \(\theta^{(1)}\)), and \(l^*(\theta^{(1)})\) (integral) points in the relative interior of the \(i\)th edge \(\theta^{(1)}_i\). Thereupon, the degree of \(\theta^{(2)}\) is obtained by counting the number of unit-area 2-simplices:

\[ d(\theta^{(2)}) = \sum_i d(\theta^{(0)}_i) - 2 + \sum_i l^*(\theta^{(1)}_i) + 2l^*(\theta^{(2)}). \tag{50} \]

Solving for \(l^*(\theta^{(2)})\), using (49) and that \(\sum_i d(\theta^{(0)}_i) = N_1\), we have:

\[ l^*(\theta^{(2)}) = \frac{1}{2}[d(\theta^{(2)}) - 2 - c(\theta^{(2)})], \quad c(\theta^{(2)}) = \sum_{\theta^{(1)}_i \subset \partial \theta^{(2)}} d(\theta^{(1)}_i), \tag{51} \]

with the sum ranging over the boundary 1-faces of \(\theta^{(2)}\), some of which may be negatively oriented and so contribute negatively. Using (51), we rewrite

\[ \left[l(\Delta_{F_m}) - 4 - \sum_{\rho=1}^{5} l^*(\Theta_\rho)\right] = \left[l(\Delta_{F_m}) - 4 - \sum_{\rho=1}^{5} \frac{1}{2}[d(\Theta_\rho) + 2 - c(\Theta_\rho)]\right]. \tag{52} \]

To this end, we need the degrees of the facets, \(d(\Theta_\rho)\), as well as the degrees of all the edges of each facet to calculate \(c(\Theta_\rho)\). For example, \(\Theta_2, \Theta_3 \subset \Delta_{F_3}\) are self-crossing; see Figure 4 for a depiction of the (coarse) star-simplex over \(\Theta_3\), shown from two points of view; the cone \(\prec(\Theta_3)\) (and \(\prec(\Theta_2)\) similarly) is self-crossing — and certainly unusual. Since \(\Theta_3\) (and \(\Theta_2\)) is a quadrangle, it can be subdivided into two (coarse) simplices: one with a positive (CCW) orientation, the other with a negative (CW) orientation; see the right-hand diagram in Figure 4. These simplicial bases overlap and partially cancel, so as to reproduce the original, self-crossing facet. Similarly, the circumference of \(\Theta_3\) is calculated by summing over the edges of \(\Theta_3\) taking into account that

\[ d([\mu_1, \mu_2, \mu_3]) = 2 - m. \]

Thus,

\[ d(\Theta_3) = d([\mu_1, \mu_2, \mu_3]) + d([\mu_2, \mu_3, \mu_4]) = 3(2+2m) + 3(2-m) = 12 + 3m, \tag{53a} \]

\[ c(\Theta_3) = d([\mu_1, \mu_2]) + d([\mu_2, \mu_3]) + d([\mu_3, \mu_4]) + d([\mu_4, \mu_1]) = 3 + (2-m) + 3 + (2+2m) = 10 + m. \tag{53b} \]

and similarly for the other facets of \(\Delta_{F_m}\).

This now allows us to calculate the number of interior points in the codimension one faces of \(\Delta_{F_m}\) using (51).

---

\(^{20}\)We thank K. Iga for independently verifying this result.

\(^{21}\)The notation \(\Theta = [\theta_1, \ldots, \theta_k]\) is intended as a generalization of an edge: the faces \(\theta_1, \ldots, \theta_k\) delimit \(\Theta\) and are in its boundary. For example, \(\Theta = [\mu_1, \ldots, \mu_\rho]\) states that “the vertices \(\mu_1, \ldots, \mu_\rho\) span (and delimit) the face \(\Theta\)”. The last step of Construction 3.1 relies on the inclusion-reversing nature of all duality relations, so that: (1) if \(\Theta = \theta_1 \cap \cdots \cap \theta_k\) then \(\Theta^\circ = [\theta_1^\circ, \ldots, \theta_k^\circ]\), i.e., \(\theta_1^\circ, \ldots, \theta_k^\circ\) delimit \(\Theta^\circ\); (2) if \(\Theta = [\theta_1, \ldots, \theta_k]\) then \(\Theta^\circ = \theta_1^\circ \cap \cdots \cap \theta_k^\circ\). Since VEX polytopes need not be convex, neither are their faces to be assumed convex, so that “to be spanned by” is not synonymous to “a convex linear combination.”
Figure 4: The star-simplex over the flip-folded facet $\Theta_3 \subset \Delta F_3$: in location within $\Delta F_3$ (left); the outward orientated “proper portion” (mid-left); $\Theta_3$ viewed from $y \ll 0$ and zooming on the “extension part” (mid-right); $\Theta_3$ subdivided into a CCW- and a CW-oriented coarse simplex (right).

Figure 5: The oriented facets $\Theta_3$, $\Theta_4$ and $\Theta_5$
Θ₂, Θ₃: From (53) and (51), l*(Θ₂) = l*(Θ₃) = 2 + m.

Θ₄, Θ₅: From Figure 5 we read off d(Θ₄) = 9 = d(Θ₅) and c(Θ₄) = 9 = c(Θ₅), which gives l*(Θ₄) = l*(Θ₅) = 1.

Θ₁: From Figure 5 we read off d(Θ₅) = 3(2−m)2 as well as c(Θ₅) = 2(3+(2−m)) = 10 − 2m, which gives l*(Θ₅) = 2 − 2m.

Putting these together, we find:

\[
\sum_{\text{codim(θ)=1}} l^*(θ) = \left[2 \cdot (2+m) + 2 \cdot 1 + (2−2m)\right] = 8. \tag{54}
\]

and thus \(\dim(\text{Aut}(\mathcal{F}_m)) = 4 + 8 = 12\), independent of \(m\).

It remains to find \(l(\Delta_{\mathcal{F}_m})\), the effective number of integral points in \(\Delta_{\mathcal{F}_m} = (\Delta_{\mathcal{F}_m}^\star)\), which

\[\sum_{\text{codim(θ)=2}} l^*(θ) = 1+2m+6 \cdot 2 + 2(1−m) = 15. \tag{56}\]

Thus, it follows that the effective number of points in the (complete) Newton polytope is

\[l(\Delta_{\mathcal{F}_m}) = 1+8+15+6 = 30. \tag{57}\]

Alternatively, we can simply count the number of points in \(\Delta_{\mathcal{F}_m}^\star\):

Figure 6: The complete Newton polytopes of the first six Hirzebruch 3-folds; see text.
1. The “standard part of $\Delta_{F_m} \leftrightarrow H^0(F_m, K^*)$ has \(^{22}30+\vartheta_3^m \cdot 4(m-3)^\bullet\) integral points. This is in perfect agreement with the result of standard homological algebra [5, Eq. (A.28)].

2. The $m \geq 3$ extensions ($\Theta_1$, the red (dark-shaded) quadrangles in Figure 6) consist of two parts:

(a) The top and bottom edge of $\Theta_1$ are $\Theta_1 \cap \Theta_4$ and $\Theta_1 \cap \Theta_5$, respectively. Those integral points count positively as belonging to $\Theta_4, \Theta_5$, but negatively as belonging to the negative-degree $\Theta_1$, and so cancel out.

(b) The outlined $4(m-3)$ integral points within the (negative-degree) $\Theta_1$, including the ones on the side that are shared with the flip-oriented edge of the self-crossing $\Theta_2$ and $\Theta_3$.

These latter $4(m-3)$ integral points contribute negatively and precisely cancel the excess integral points in the rising tip of the standard part of $\Delta_{F_m}$.

The net result is that the oriented Newton polytope $\Delta_{F_m} := (\Delta_{F_m}^\ast)^\ast$ encodes an effective number of 30 elements of $H^0(F_m, K^*)$. Summarizing the calculation, the contributions from the growing “tip” of the positively oriented portion of the Newton polytope and the growing negatively oriented extension cancel in just the same way also for Calabi-Yau hypersurfaces in Hirzebruch 2- and 4-folds [23]. Thus, the number of toric deformations is

$$\left[ l(\Delta_{F_m}) - 4 - \sum_{\rho=1}^{5} l^\ast(\Theta_\rho) \right] = \left[ 30 - 4 - 8 \right] = 18. \quad (58)$$

**Correction term:** Finally, the “correction term,” $\sum_{\theta} l^\ast(\theta) l^\ast(\theta^\ast)$ ranging over codimension-2 faces $\theta \subset \Delta_{F_m}$, identically vanishes. To see this, note that $\theta^\ast$ are edges in the spanning polytope $\Delta_{F_m}^\ast$, all of which have positive unit degree, and no internal points by (49); with all $l^\ast(\theta^\ast) = 0$, the sum vanishes.

Putting (48), (58) and zero for the third, “correction” term in (46), we obtain:

$$h^{1,1}(K3 \subset F_m) = 2 + 18 + 0 = 20, \quad (59)$$

as expected for a $K3$ surface.

**B.2 Calabi-Yau three-folds**

We now turn to calculating the degrees of the various faces in the pair of polytopes $(\Delta_{F_m}, \Delta_{F_m}^\ast)$, for $m \geq 3$.

**dim $\theta, \theta^\ast = 1$:** The edges $\theta^\ast = \theta^\ast$ in the spanning polytope $\Delta_{F_m}^\ast$, all have unit length so unit degree, $d(\theta^\ast) = 1$. Turning next to the edges $\theta$ in the Newton polytope $\Delta_{F_m}$ we have:

1. one “vertical” edge, $[(-1, -1, -1, -1)]$, of degree $d(\theta) = 2 + 3m$;
2. three “horizontal” edges of degree $d(\theta) = 4$ each, from $(-1, -1, -1, -1)$ to one of an extension, top: $(-3, -1, -1, -1), (-1, 1, -1, -1), (-1, -1, 3, -1);$ (60)
3. three “slanted” edges of degree $d(\theta) = 4$ each, from $(-1, -1, -1, 3m)$ to one of an extension, bottom: $(-3, -1, -1, 1-m), (-1, 1, -1, -1-m), (-1, -1, 3, 1-m)$. (61)

\(^{22}\)The symbol $\vartheta^m_x := 1$ if $x \leq y$ and $\vartheta^m_x := 0$ if $x > y$ is the usual step-function.
4. In the extension part of the Newton polyhedron we have two sets of three “horizontal” edges, connecting two of three vertices on the top (60), and two of the three vertices on the bottom (61), each edge of degree $d(\theta) = 4$.

5. Finally, there are the three “vertical” negative-degree edges, each of which connects one of the three top vertices (60) to the corresponding one of the three bottom vertices (61). Each of these “vertical” edges is of length $(m-2)$, but has negative degree $d(\theta) = -(m-2)$, as they manifestly extend in the direction opposite of the corresponding edges in the (convex) Newton polytope when $m \leq 2$.

**dim $\theta, \theta^* = 2$:** The faces $\theta^* = \theta^\gamma$ in the spanning polytope $\Delta_{F_3}$ all have nominal area and so unit degree, $d(\theta^*) = 1$. In order to assess $\theta \subset \Delta_{F_3}$ in the Newton polytope, we proceed in a manner similar to the analysis of the 2-faces for K3:

1. There are three large “vertical” and flip-folded (self-crossing) quadrangular faces $\theta \subset \Delta_{F_3}$ (analogous to $\Theta_2$, $\Theta_3 \subset \Delta_{F_3}$ in Figure 3):

   \[((-1, -1, -1, -1), (-1, -1, -1, 1+3m), (3, -1, -1, 1-m), (3, -1, -1, -1)], \]
   \[((-1, -1, -1, -1), (-1, -1, -1, 1+3m), (3, -1, -1, 1-m), (3, -1, -1, -1)], \]
   \[((-1, -1, -1, -1), (-1, -1, -1, 1+3m), (3, -1, -1, 1-m), (3, -1, -1, -1)], \]

   The area of each of these three flip-folded (self-crossing) faces has two contributions in analogy with the similar calculation for the degree in the $n = 3$ case (see Figure 4), and is $d(\theta) = (2+3m)\cdot 4+(2-m-4 = 8(2+m)$. The circumference is similarly given by $c(\theta) = 4+(2-m)\cdot 4+(2+3m)=2(6+m)$, since the degree of the vertical edge is $(2-m)$ and thus $\frac{1}{2}(d(\theta) - c(\theta)) = 2 + 3m$.

2. Next, we have three “horizontal” faces (analogous to $\Theta_4$ in Figure 3):

   \[((-1, -1, -1, -1), (3, -1, -1, 1), (-1, 3, -1, -1)], \]
   \[((-1, -1, 1, 1), (3, -1, -1, -1), (-1, -1, 3, -1)], \]
   \[((-1, -1, -1, -1), (-1, 3, -1, -1), (-1, -1, 3, -1)], \]

   and three “slanted” faces (analogous to $\Theta_5$ in Figure 3):

   \[((-1, -1, 1+3m), (3, -1, -1, 1-m), (-1, 3, -1, 1-m)], \]
   \[((-1, -1, 1+3m), (3, -1, -1, 1-m), (-1, 3, 1, 1-m)], \]
   \[((-1, -1, 1+3m), (3, -1, -1, 1-m), (-1, 3, 1, 1-m)], \]

   They are all simplices with the degree $d(\theta) = 4\cdot 4 = 16$ since they have height four and base four. Since each of the edges in the above faces have degree 4, it immediately follows that $c(\theta) = 3\cdot 4 = 12$, and so $\frac{1}{2}(d(\theta) - c(\theta)) = 2$.

3. Finally, the extension of the Newton polytope (analogous to $\Theta_1$ in Figure 3) is now a 3-sided prism. This has two triangular faces which contribute with positive degree:

   \[((-1, -1, -1, -1), (3, -1, -1, -1), (-1, 3, 1, -1)]_{\text{top}} \]
   \[((-1, -1, -1, -1), (3, -1, -1, -1), (-1, 3, 1, -1)]_{\text{bottom}}, \]

   each having degree $d(\theta) = 16$ and circumference $c(\theta) = 12$, with $\frac{1}{2}(d(\theta) - c(\theta)) = 2$, as in the previous case. The three vertical rectangular walls of the 3-sided prism

   \[((-1, 3, -1, -1), (-1, 3, -1, -1), (3, -1, 1, 1-m)], \]
   \[((-1, 3, -1, -1), (-1, 3, -1, -1), (3, -1, 1, 1-m)], \]
   \[((-1, 3, -1, -1), (-1, 3, -1, -1), (3, -1, 1, 1-m)], \]

   each having degree $d(\theta) = 16$ and circumference $c(\theta) = 12$, with $\frac{1}{2}(d(\theta) - c(\theta)) = 2$, as in the previous case.
have negative degrees, each equal to \(d(\theta) = (2-(1-m)\cdot 4) = -8(m-2)\). They generalize the two vertical edges \([\mu_4, \mu_3]\) and \([\mu_6, \mu_5]\) in the \((n=3)\)-dimensional case depicted in Figure 3. Similarly, the circumference is then given by \(c(\theta) = 2\cdot 4 + 2\cdot (2-m) = 2(6-m)\). Thus, we have that \(\frac{1}{2}(d(\theta) - c(\theta)) = 2 - 3m\).

With the degrees for the 1- and 2-faces calculated, we first compute the Euler number. The contribution from the edges \(\theta \subset \Delta_{F_3}\) and their polar 2-faces \(\theta^* \subset \Delta^*_{F_m}\) becomes

\[
\sum_{\dim \theta = 1} d(\theta) \, d(\theta^*) = 1\cdot (3m+2) + 3\cdot (4) + 3\cdot (4) + 2\cdot 3\cdot (4) + 3\cdot [-(-m-2)] = 56, \tag{67}
\]

while that of the 2-faces \(\theta \subset \Delta_{F_3}\) and their polar edge \(\theta^* \subset \Delta^*_{F_3}\) is similarly given by

\[
\sum_{\dim \theta = 2} d(\theta) \, d(\theta^*) = 3\cdot [8\cdot (2+m)] + 3\cdot 2\cdot (16) + 2\cdot (16) + 3\cdot [-8\cdot (m-2)] = 224. \tag{68}
\]

Thus, we find that \(\chi = 56 - 224 = -168\) in agreement with the gCICY result \([1, 5]\).

Next, we turn to the Hodge numbers, \(h^{1,1}\) and \(h^{2,1}\), respectively. For \(n = 4\), there are \(N_0^* = 6\) vertices in \(\Delta^*_{F_m}\) and \(N_0 = 8\) vertices in \(\Delta_{F_m}\). Thus, from our calculation of the degrees above we find

\[
\sum_{\dim \theta = 1} d(\theta) + \sum_{\dim \theta^* = 1} d(\theta^*) = 1\cdot (3m+2) + 12\cdot 4 + 3\cdot (2-m) + 14\cdot 1 = 70; \tag{69}
\]

\[
N_0^* - N_1^* + \frac{1}{2} \sum_{\dim \theta = 2} (d(\theta) - c(\theta)) d(\theta^*) = 6 - 14 + \frac{1}{2}\left(-2\right)56 = -64; \tag{70}
\]

\[
N_0 - N_1 + \frac{1}{2} \sum_{\dim \theta = 2} (d(\theta) - c(\theta)) d(\theta^*) = 8 - 16 + 3(2+3m) + 6\cdot 2 + 2\cdot 2 + 3(2-3m) = 20. \tag{71}
\]

Thus, it then follows from (39) and (38) that \(h^{1,1} = 70 - 4 - 64 = 2\) and \(h^{2,1} = 70 - 4 + 20 = 86\), again in agreement with the gCICY result \([1, 5]\).

As a further check, we can also calculate \(h^{2,1}\) in the following way. Consider the Newton polytope for \(F_m\), as discussed in Section 4.2. Excluding the \(z = (1-m)\) and \(z = -1\) triangles (where the extension intersects with positively oriented ordinary facets), this contains \(15(m-3)\) integral points within the negatively oriented extension. In turn, it is straightforward to show by explicit counting that the positively oriented portion of the Newton polytope has \(105 + \theta_3^m 15(m-3)\) integral points. These two \(m\)-dependent contributions therefore identically cancel for all \(m\).

In turn, the corner edges of the extension,

\[
\{(3, -1, -1, z), \ (1, -3, -1, z), \ (-1, -1, 3, z), \ \text{with} \ (1-m) \leq z \leq -1\} \tag{72}
\]

contain \(3(m-1)\) points where the negatively oriented extension intersects with flip-folded (self-crossing) facets at the portions where those other facets are themselves negatively oriented. Owing to this double negative, these points count as deformations of the complex structure of \(F_m\) itself, and are being canceled precisely by the surplus reparametrizations \([5]\). This renders the Hirzebruch 4-folds effectively rigid.

We thus remain with the effective number of 105 anticanonical sections, 18 reparametrizations and one overall scaling of the equation defining the hypersurface, producing the expected result: \(105 - 18 - 1 = 86 = h^{2,1}(Y_m)\) for the Calabi-Yau 3-fold \(Y_m \subset F_m\) \([5]\).
