Abstract: PEMFC are considered to be the most promising for automotive energy because of their good working effect, low temperature, high efficiency, and zero pollution. Stainless steel as a PEMFC bipolar plate has unparalleled advantages in strength, cost, and processability, but it is easy to corrode in a PEMFC working environment. In order to improve the corrosion resistance, the surface modification of 316L stainless steel is a feasible solution for PEMFC bipolar plates. In the present study, the plasma-nitrided coating and CrN\textsubscript{x} coating were prepared by the plasma-enhanced balanced magnetron sputtering technology on the 316L stainless steel surface. The microstructures, phase compositions, and corrosion resistance behavior of the coatings were investigated. The corrosion behavior of the prepared plasma-nitrided coating and CrN\textsubscript{x} coating was investigated by potentiodynamic polarization, potentiostatic polarization, and electrochemical impedance spectroscopy (EIS) in both cathodic and anodic environments. The experimental results show that corrosion resistance of the CrN\textsubscript{x} coating was better than the plasma-nitrided coating. It was indicated that the technology process of nitriding first and then depositing Cr was better than nitriding only.

Keywords: bipolar plate; magnetron sputtering; plasma-nitrided coating; CrN\textsubscript{x} coating; corrosion resistance

1. Introduction

Fuel cells are electrochemical devices that convert the chemical energy of a reaction directly into electrical energy [1]. PEMFC is one of the most promising candidates for vehicular power sources and for domestic combined heat and power (CHP) systems. The PEMFC operates at a low temperature (60–80 °C) and has a high specific power and compactness. It consisted of membrane electrode assembly and bipolar plates. Bipolar plates are one of the core components of PEMFC and provide electrical connections from one battery to another. They also evenly distribute reaction gases through the flow field, conduct current from each cell, and promote residual water discharge from the cell outlet for thermal management [2–5]. It is proved that bipolar plates account for 80%–85% of the total weight and 30% of the total cost of PEMFC stacks [6,7]. Therefore, it is important to simultaneously reduce the weight and the cost of bipolar plate materials. Bipolar plates possess the characteristics of high chemical stability, high corrosion resistance, high conductivity, low contact resistance, good mechanical strength, and low permeability. However, very few materials can satisfy all these properties of bipolar plates [8–10]. Stainless steel is the most commonly used bipolar plate material, but it easily forms a passive film in the bipolar plate working environment, which caused an increase in the contact resistance and a reduction in the corrosion resistance of bipolar plates. Therefore, a coating with strong adhesion, compact structure, good corrosion resistance, and strong conductivity is usually prepared on the stainless steel surface [11–15].
Different surface modification techniques, such as physical vapor deposition (PVD) [16–21], chemical vapor deposition (CVD), plasma coating [22], and surface plasma nitridation [23–26], have been employed to deposit coatings on the stainless steel surface. Plasma-nitrided PVD coatings can increase the corrosion resistance and also significantly reduce the contact resistance of bipolar plates. Oladjo et al. [27] employed the plasma spraying technology to deposit a zinc-based alloy coating on the low-carbon steel matrix and found that zinc-based alloy coated low-carbon steel yielded improved corrosion resistance and microhardness in comparison to uncoated low-carbon steel. Metal plasma nitrides (CrN, TiN, and Cr/TiN) with good corrosion resistance, excellent interface conductivity, and low cost [28–30] are known as potential materials for surface modification. Zhang et al. [31] reported that when the contact resistance of the hard CrN coating reached the minimum value, the nitrogen content in the coating was about 35% [32–37].

In this study, the plasma-nitrided coating and CrN coating are deposited on 316L stainless steel by plasma-enhanced balanced magnetron sputtering technology. The microstructure and phase structure patterns of coatings are investigated by scanning electron microscope (SEM) and X-ray diffraction. The corrosion behavior of the plasma-nitrided and CrN coating are coated on the 316L stainless steel and is investigated by the electrochemical method. The ICR is also evaluated before and after potentiostatic polarization at anodic/cathodic operation potential for PEMFC. The performance of corrosion resistance and surface morphologies of the plasma-nitrided coating and CrN coating were compared.

2. Experimental

2.1. Materials and Specimen Preparation

316L austenitic stainless steel was selected as the matrix, and its chemical composition is presented in Table 1. The 316L austenitic stainless steel matrix was first cut into φ30 mm × 3 mm cylinders by wire cutting. The samples were then put into a mixed solution of ethanol and acetone for ultrasonic cleaning. After that, the samples were polished on the polishing machine at a constant speed for 3–4 min at one third of the center of the circle, and then water polishing for 2 min until there is no obvious scratch on the surface. Subsequently, the samples were cleaned in acetone with ultrasonic vibration for 10 min.

| Component | C  | Si | Mn | P   | Cr | Ni | Mo | Fe     |
|------------|----|----|----|-----|----|----|----|--------|
| Content (%)| ≤0.08 | ≤1 | 2–3 | ≤0.035 | 16–18.5 | 10–14 | 2–3 | balance |

2.2. Deposition of the Coating

Plasma-nitrided coating and CrN coating were deposited on 316L stainless steel by magnetron sputtering technology. The plasma-nitrided coating was deposited under an N₂ gas nitrogen flow of 200 sccm at 380 °C, a filament current 6 A, and deposition time of 2 h. The CrN coating is prepared on the basis of the plasma-nitrided coating. After the plasma-nitrided coating was prepared, the CrN coating was deposited under an Ar gas flow of 100 sccm and the deposition time of 10 min. The plasma-nitrided coating was formed on the stainless steel first, and the Cr layer was formed on the nitriding layer. All specimens were cooled to room temperature in vacuum conditions.

2.3. Electrochemical and Contact Resistance Tests

In the simulated PEMFC environment, an AutoLab electrochemical workstation (CHI600E, Japan Shimadzu Co., Ltd., Tokyo, Japan) was used to test the corrosion resistance of the matrix and the coatings through potentiodynamic polarization, potentiostatic polarization, and impedance spectroscopy (EIS). In the present experiment, a three-electrode system was used. The sample acted as the working electrode (WE), the platinum electrode served as the counter electrode (CE), and the saturated calomel
electrode acted as the reference electrode (RE). The solution (0.5 mol/L H₂SO₄ + 5 ppm HF) was used to simulate the corrosive environment of PEMFC during the experiment. The method for measurement of the ICR between stainless steel and gas diffusion layer (carbon paper) described by Feng et al. [38] was used in this study. When an electrical current (100 mA) was passed through the two copper plates, the voltage between the two copper plates was recorded. The ICR was calculated by the Ohm’s law.

2.4. Surface Morphology Analysis

The microstructure and chemical composition of the samples were investigated by a scanning electron microscope (SEM, JSM-6390A, Joint-stock Company, Beijing, China) and an energy dispersive spectrometer (EDS, JSM-6390A, Joint-stock Company, Beijing, China). Chemical structures of coatings were investigated by X-ray diffraction (XRD, LabX XRD-6000, Japan Shimadzu Co., Ltd., Tokyo, Japan) under a scanning angle of 30°–110°.

3. Results and Discussion

3.1. Phase Constitution of the Coating

Figure 1 showed XRD patterns of the 316L plasma-nitrided samples under different bias voltages. The XRD patterns of 316L stainless steel had the diffraction peaks of γ(111), γ(200), γ(220), γ(311), and γ(222). The diffraction peaks of γ₅N(311) and γ₅N(222) became wide after plasma nitriding, whereas the diffraction peak intensities of γ₅N(111) and γ₅N(200) increased. The diffraction peaks of all plasma-nitrided samples moved to the left and became asymmetric. The preferred orientations of the samples after plasma nitriding were still γ₅N(111) and γ₅N(200). Both the γ₅N and γ phases in 316L stainless steel after plasma nitriding possessed a face-centered cubic structure. Interstitial N atoms entered the lattice interior and formed a supersaturated solid solution in austenite in 316L stainless steel [39]. The broadening of the diffraction peaks of γ₅N(111) and γ₅N(200) and the shift of all diffraction peaks to the left can be attributed to the occurrence of surface slips and the generation of the high stacking fault density in the crystal after plasma nitriding. With the increasing bias voltage, the bombardment energy increased, and the diffraction peaks of γ₅N(111) and γ₅N(200) tended to shift to a small angle. With the increasing energy, the surface of 316L stainless steel was activated, the matrix etching was increased, and the 316L passivation film was removed, thus increasing the diffusion of nitrogen atoms in austenite and causing the shift in the diffraction peaks. The diffraction peaks of CrN and Cr₂N were not found in the XRD patterns, which indicated that no martensite and plasma-nitride precipitation appeared during low-temperature plasma nitriding. Therefore, the corrosion resistance of the plasma-nitrided coating became better.

![Figure 1. X-ray diffraction (XRD) patterns of the plasma-nitrided coating under different bias voltages.](image)

Figure 2 shows the XRD patterns of the CrNₓ coating under different filament currents. With the increasing filament current, CrN grew along the CrN(111) and CrN(200) directions. The diffraction peaks of Cr₂N(111), CrN(200), and Cr(110) appeared when the filament current was 3 A and the value...
of 2θ was between 40° and 45°. With the increasing filament current, the intensity of the Cr(110) diffraction peak decreased, and the Cr₂N(111) diffraction peak changed to CrN(200). When the filament current was 5 A and the value of 2θ was between 60° and 65°, the diffraction peaks of Cr and CrN appeared. The diffraction peak of Cr₂N(211) first increased and was then transformed to the CrN(220) peak. In comparison to the standard card peak positions, some diffraction peaks deviated slightly from the Bragg angle, so it proved that the lattice distortion was small, and the grain integrity was high.

The Rietveld whole pattern fitting was allowed to estimate the lattice parameters and the average crystallite size of the powders (Table 2) [40]. Rietveld evaluations should be considered only as estimations, as the fitting results were not completely satisfactory, irrespective of the efforts dedicated to this specific task. For the plasma-nitried coating, the quantitative assessments suggested that the a-lattice parameter and b-lattice parameter (a = 6.9623–6.97597 Å, b = 6.9623–6.97597 Å) and the average crystallite size remained virtually constant (41.63–41.98 nm), while the c-lattice parameter was only slightly increased in the case of the voltage of −500 V. For the CrNₓ coating, when the filament current was 4 A, the quantitative assessments suggested that the c-lattice parameter (c = 4.58199–4.5841 Å) remained virtually constant, while the a-lattice parameter, b-lattice parameter (a = 4.58119–4.8113 Å, b = 4.58119–4.8113 Å), and the average crystallite size (8.94–9.61 nm) was slightly increased.

### Table 2. Lattice parameters and average crystallite size for the plasma-nitried coating and CrNₓ coating under different condition grains (as extracted by Rietveld whole pattern fitting).

| Sample Tape | a-Lattice Constant (Å) | b-Lattice Constant (Å) | c-Lattice Constant (Å) | Average Crystallite Size (Å) |
|-------------|------------------------|------------------------|------------------------|-----------------------------|
| −400 V      | 6.9623 ± 0.006         | 6.9623 ± 0.006         | 9.9381 ± 0.005         | 417.20                      |
| −500 V      | 6.97597 ± 0.002        | 6.9759 ± 0.002         | 9.96191 ± 0.004        | 419.84                      |
| −600 V      | 6.96761 ± 0.015        | 6.9676 ± 0.015         | 9.90159 ± 0.019        | 416.30                      |
| 3 A         | 4.58119 ± 0.001        | 4.5811 ± 0.001         | 4.58119 ± 0.001        | 89.89                       |

| 5 A         | 4.81079 ± 0.007        | 4.8107 ± 0.007         | 4.56199 ± 0.033        | 89.40                       |

### 3.2. Morphology of the Coating

Figure 3 showed the surface morphologies of the plasma-nitried coating under different bias voltages and expressed that twin diffraction peaks presented in the plasma-nitried coating. With the increasing bias voltage, the amount of surface “cross grains” increased and the grain boundary became prominent with a small number of twins. The ion energy and the bombardment degree increased with the increasing bias voltage. The main features of the plasma-nitried coating surface were its sharp grain boundary, large area of sliding, and large number of “moving steps.” The sharp grain boundary might occur due to the selective sputtering of nitrogen during the sputtering process. In addition, the anisotropy of the material was observed when nitrogen caused an expansion in the
austenite crystal. The slip occurred due to the surface deformation caused by the anisotropic lattice expansion in the plasma-nitrided coating. When the bias voltage was ~500 V, the surface of the sample was uniform and had some non-obvious grain boundaries and less striation due to the strong etching of excessive sputtering. Ion sputtering acts like an invisible knife and can peel off the surface molecules of a sample. When the plasma-nitriding bias voltage was ~500 V, the energy and density of nitrogen in the cavity increased simultaneously due to ion sputtering. In comparison, when the bias voltage was ~400 V, the mild ion sputtering selectively etched grain boundaries, which caused the samples rough surfaces. When the bias voltage was ~600 V, defects appeared at grain boundaries due to the significant increase in substance energy. Moreover, a large anisotropic lattice distortion of nitrogen substances was observed in the plasma-nitrided coating.

![Figure 3](image1.png)

**Figure 3.** Surface morphologies of the plasma-nitrided coating under different bias voltages: (a) ~400 V, (b) ~500 V, (c) ~600 V.

Figure 4 showed surface morphologies of CrN\textsubscript{x} coating under different filament currents. As could be seen in Figure 4, the surface of the CrN\textsubscript{x} coating, produced by magnetron sputtering, was homogeneous, devoid of variations, being covered evenly with grains, as could be seen in Figure 4. The grains that cover the surface were arranged regularly without voids, forming a compact film. In Figure 4, it can clearly be seen that these coating grains were formed of particles with micrometer dimensions. It was indicated in Figure 4 that grains on the CrN\textsubscript{x} coating were in the form of long strips. With the increasing filament current, long grains gradually changed into cellular ones and less space existed between them. However, when the filament current was 5 A, the gap between grains again became large, and the amount of strip-shaped grains increased significantly. The increase in the filament current raised the surface temperature of grains, increased the bombardment energy of particles, increased the sputtering speed of Cr particles, increased the nucleation rate of Cr particles, and refined the grains. N particles filled the gap at the grain boundary and prevented F\textsuperscript{−}, SO\textsubscript{4}\textsuperscript{2−} and other ions in the electrolyte from the invading CrN\textsubscript{x} coating. However, when the current density of the filament was too high, the bombardment energy to the target increased, so the sputtering speed was too fast. The deposition of Cr particles was homogeneous, and N particles could not fill grain boundary pores, so corrosive substances in the electrolyte entered the inner part of the coating through grain boundary pores and caused a reduction in corrosion resistance.

![Figure 4](image2.png)

**Figure 4.** Surface morphologies of the CrN\textsubscript{x} coating under different filament currents: (a) 3 A, (b) 4 A, (c) 5 A.

Figure 3 showed that there were defects at the grain boundary of the plasma-nitried coating and the surface of the plasma-nitried coating is rough. Compared with the plasma-nitried coating,
the CrN$_x$ coating was more uniform and tiny. No pits or corrosion deposits are observed in the CrN$_x$ coating.

3.3. Electrochemical Measurements

3.3.1. Electrochemical Measurements of the Plasma-Nitrided Coating

Figure 5 showed potentiodynamic polarization curves of the plasma-nitrided coating in the working environment of the PEMFC bipolar plate. The plotted curves consisted of an activated solution region, an activated passivation region, a passivation region, and an over passivation region after the plasma-nitriding treatment [41]. The range of the activation passivation zone of the sample increased significantly after plasma nitriding because the cathode potential was lower than the corrosion potential of the metal when air was purged into the simulated working environment of the PEMFC cathode and a passivation layer was easily formed on the metal surface. This process mainly occurred in the activation passivation region, so the curve range of the activation passivation region became larger. At the same $E_{corr}$, the $I_{corr}$ value of the matrix was the smallest. When the bias voltage was $-500$ V, the corrosion current density of the plasma-nitrided coating was the smallest (0.907 $\mu$A·cm$^{-2}$).

![Figure 5](image-url)

**Figure 5.** Potentiodynamic polarization curves of the plasma-nitrided coating in the working environment of the PEMFC bipolar plate ((a) cathodic working environment, (b) anodic working environment).

In the simulated working environment of the PEMFC anode, the range of the active solution area of the potentiodynamic polarization curves was very large and the active–passive area almost disappeared after plasma nitriding. The reason was most of hydrogen dissolved in the electrolyte of simulated anodic environment. H$^+$ in the solution reacted with nitrogen in the plasma-nitrided coating and promoted the adsorption of H$_2$ on the anode and accelerated the corrosion reaction. In addition, metal elements became ions after being dissolved in the anode and got attached to the catalyst surface to reduce their activity, so the active dissolution region became longer. In the anodic environment, with the increasing matrix bias voltage, the corrosion current density of the plasma-nitrided coating did not change significantly. The corrosion potential had a positive shift that increased first and then decreased. When the bias voltage was $-500$ V, the $E_{corr}$ of the plasma-nitrided coating attained the largest value of 0.307 V, and the $I_{corr}$ value was 5.215 $\mu$A·cm$^{-2}$.

Figure 6 showed the Nyquist curves of 316L stainless steel in the selected bias voltage range. Each impedance arc was composed of only one capacitive reactance arc in the high-frequency region. As the diameter of the capacitive arc and the $R_t$ value on the electrode surface are related to metal dissolution, the corrosion resistance of a material gets improved for a larger capacitive arc. The diameter of the capacitive arc was the largest when the bias voltage was $-500$ V, so the corrosion resistance of the coating was better.
working environment. When the filament current values were 3, 4, and 5 A, the active dissolving working environment of the PEMFC bipolar plate. The passivation range of the potentiodynamic polarization curve of the CrN coating was similar to that of the matrix, but the corrosion current density was greatly reduced. Figure 7 showed Potentiodynamic polarization curves of the CrN coating in the working environment of the PEMFC bipolar plate. The passivation range of the potentiodynamic polarization curve of the CrN coating was similar to that of the matrix, but the corrosion current density was greatly reduced. Figure 7a showed potentiodynamic polarization curves in the cathodic working environment. When the filament current values were 3, 4, and 5 A, the active dissolving area increased and was larger than that of the matrix. However, the CrN coating entered a stable passivation area after passing through the extremely narrow activation passivation area and indicated that the CrN coating could self-passivate in the solution. The best corrosion resistance of the coating was obtained when the filament current was 4 A ($E_{corr} = -0.043 V, I_{corr} = 0.321 \mu A \cdot cm^{-2}$).

### 3.3.2. Electrochemical Measurements of the CrN$_x$ Coating

The effect of manufacturing conditions on the corrosion resistance of 316L was discussed in another study by authors earlier [42]. Ma et al. studied even few ppm (5–10) of metal ions can poison the membrane of PEM-type fuel cell [43]. So, the research on the corrosion resistance of the CrN$_x$ coating is very important. Figure 7 showed Potentiodynamic polarization curves of the CrN$_x$ coating in the working environment of the PEMFC bipolar plate. The passivation range of the potentiodynamic polarization curve of the CrN$_x$ coating was similar to that of the matrix, but the corrosion current density was greatly reduced. Figure 7a showed potentiodynamic polarization curves in the cathodic working environment. When the filament current values were 3, 4, and 5 A, the active dissolving area increased and was larger than that of the matrix. However, the CrN$_x$ coating entered a stable passivation area after passing through the extremely narrow activation passivation area and indicated that the CrN$_x$ coating could self-passivate in the solution. The best corrosion resistance of the coating was obtained when the filament current was 4 A ($E_{corr} = -0.043 V, I_{corr} = 0.321 \mu A \cdot cm^{-2}$).

**Figure 6.** Electrochemical impedance spectroscopy (EIS) analysis of the plasma-nitrided coating under different bias voltages.

**Figure 7.** Potentiodynamic polarization curves of the CrN$_x$ coating in the working environment of the PEMFC bipolar plate, (a) cathodic working environment, (b) anodic working environment.

Figure 7b showed potentiodynamic polarization curves in the anodic working environment. The activated solution area of the coated sample increased greatly, and the activated passivation area was very short, the corrosion current density was reduced, and the corrosion potential almost moved forward. With the increasing filament current, the active dissolving region first increased and then decreased gradually. Mobile nitrogen particles reacted with H$^+$ in the electrolyte promoted the adsorption of H$_2$ on the anode and accelerated the corrosion reaction. When nitrogen elements in the sample were exhausted, the corrosion current density decreased greatly, and the phenomena of metal...
dissolution and oxidation occurred, so the unstable activation passivation region almost disappeared. With the increasing filament current, the corrosion current density of the CrNₓ coating decreased first and then increased. When the filament current was 4 A, the corrosion current density of the CrNₓ coating was the lowest (1.881 µA-cm⁻²), the corrosion current density was the most positive. The corrosion current density was the smallest under a filament current density of 5 A because the lattice distortion increased and the preferred orientation changed greatly with the increasing filament current. The transition from CrN(200) to CrN(100) resulted in the change in the composition of the potentiodynamic polarization curve. Nitrogen elements made the metal passivate rapidly, so a fluctuation between the activation passivation region and the stable passivation region occurred and the stable passivation region was wider than those of other curves when the filament current was 5 A.

When the temperature is 80 °C, 99.999% hydrogen and air were purged into the electrolyte to simulate the anodic and cathodic environments of the PEMFC bipolar plate. Figure 8a shows potentiostatic polarization curves in the cathodic working environment. In the first minute, the current first decreased greatly and then became stable. The current densities of the coated samples were lower than that of the 316L stainless steel matrix, and the difference of corrosion current was not significant. When the filament current was 4 A, the corrosion current was smallest (4.136 µA). Figure 8b shows the potentiostatic polarization curve in the anodic working environment. In the first two minutes, the current decreased significantly and then tended to be stable. When the current was stable, the current density of the constant potential polarization curve at the filament current of 4 A was smallest (−3.534 µA). No obvious changes were observed on sample surfaces before and after the test, and the deposited CrNₓ coating had high stability.

![Figure 8. Potentiostatic polarization curves of the CrNₓ coating in the working environment of the PEMFC bipolar plate (a) cathodic working environment, (b) anodic working environment.](image-url)

Figure 9 shows an EIS analysis of CrNₓ coating under filament currents. Figure 9 illustrates that the trend of impedance diagrams of different filament current densities was the same. All curves were composed of a semicircle of the high frequency part and a linear function curve of the low frequency part. However, the curves of semicircles were not standard semicircles, but slightly expanded semicircles. From the linear part, the slopes of these linear functions were all positive numbers. When changing the filament current density, the gradient of the linear part in the Nyquist curve of the sample was the same, and the angle between the linear part and the horizontal axis in the figure was about 60°, which showed that changing the filament current density was not change the control steps and mechanism of the electrochemical reflection of the coating. Based on the Warburg impedance characteristics and coating performance analysis, it was speculated that the electrochemical corrosion of the matrix is relatively severe. In the later stage of corrosion, the surface CrNₓ coating and the bubble area at the CrNₓ interface had a larger porosity and the Cr layer was corroded. Brady et al. [44] showed that the diffusion process of the surface was equivalent to the spherical diffusion, resulting in the gradient value of the linear part greater than 1.
The CrN coating had low density and possessed numerous pores, so corrosive ions in the electrolyte easily entered the coating to cause intergranular corrosion. Liu et al. [45] showed that the sputtering speed affected the adhesion of N and Cr particles. However, when the current density was too high, the target energy was also too high, and the sputtering speed of Cr particles was too fast and N particles could not fill grain boundary pores, so corrosive substances in the electrolyte entered the coating through grain boundary pores to cause corrosion.

Figure 9 showed the Bode curves of CrN coating under different filament currents. All curves in the impedance frequency diagram (Figure 10a) and the phase-angle frequency diagram (Figure 10b) had a similar trend. When the filament current density was 4 A, the impedance mode value was the largest, and the corrosion resistance of the sample was better. In Figure 10b, the phase-angle frequency curve of the matrix has only one peak, whereas CrN coating has two peaks (representing two time constants). When the filament current density was 4 A, the phase angle was the largest, and the corrosion resistance of the coating (close to 70°) was better.

**Figure 9.** EIS analysis of CrN coating under different filament currents.

It was indicated from Figure 9 that the semicircle diameter on the Nyquist diagram was the largest when the filament current density was 4 A. When the current density was too small, the bombarding energy was small, the number of deposited particles was less, and the distribution of CrN on the coating surface was uniform. However, the final sample first reacted with the CrN coating and then with the Cr layer. The CrN coating had low density and possessed numerous pores, so corrosive ions in the electrolyte easily entered the coating to cause intergranular corrosion. All the results illustrated that when the filament current was 4 A, the CrN coating had good corrosion resistance.

**Figure 10.** Bode curves of the CrN coating under different filament currents ((a) Impedance mode value (|Z|) versus frequency (f) curves, (b) Phase angle versus frequency (f) curves).

Figure 11 showed the equivalent analog circuit diagram of EIS under different filament currents. Table 3 showed the EIS equivalent circuit fitting results under different filament currents. All the results illustrated that when the filament current was 4 A, the CrN coating had good corrosion resistance.
3.3.3. Corrosion Resistance of Coatings

The plasma-nitrided coating and CrN<sub>x</sub> coating performed good corrosion resistance when the bias voltage was ~500 V and the filament current was 4 A. In the Potentiodynamic polarization test, the corrosion current densities of the plasma-nitrided coating and CrN<sub>x</sub> coating were 0.907 and 0.312 µA·cm<sup>−2</sup> in the cathodic environment and 5.215 and 1.881 µA·cm<sup>−2</sup> in the anodic environment. So, the plasma-nitrided coating and CrN<sub>x</sub> coating had better corrosion resistance in the cathode environment than in the anode environment due to passivation of metals [46]. So, the corrosion resistance of the CrN<sub>x</sub> coating was better than the plasma-nitrided coating. It was indicated that the technology process of nitriding first and then depositing Cr was better than nitriding only.

3.4. Contact Resistance of the CrN<sub>x</sub> Coating

Figure 12 shows the contact resistances of the CrN<sub>x</sub> coating under different filament currents. With the increase of the pressure per unit area, the contact resistance decreased sharply at the beginning and then changed smoothly and became stable at a pressure above 1.4 MPa. However, when the filament current was 3 A, the contact resistance was always much higher than those under other conditions. During the period of gentle change, the smallest contact resistance was obtained when the filament current was 4 A (7.64 mΩ·cm<sup>−2</sup>).
When 316L stainless steel was in contact with air, thin films of iron oxide and chromium oxide were formed on its surface. These oxide films could not improve the corrosion resistance of stainless steel, but they increased the interface contact resistance. Wu et al. [47] showed that the compositions of these oxide films were greatly improved after plasma nitriding, so the corrosion resistance of the sample was also improved. When the filament current was 3 A, the coating was composed of CrN and Cr₂N. However, when the filament current values were 4 and 5 A, Cr₂N was completely converted into CrN. It was speculated that the difference in contact resistance at different filament currents occurred from different plasma-nitrided structures.

4. Conclusions

316L stainless steel surfaces were coated by the plasma-enhanced balanced magnetron sputtering. The XRD patterns indicated the presence of Cr, CrN, and Cr₂N in the CrNx coating. The Rietveld whole pattern fitting was allowed to estimate the lattice parameters, the results showed that the average crystallite size of CrNx coating were better. The microstructures indicated that there were defects at the grain boundary of the plasma-nitrided coating and that the surface of the plasma-nitrided coating was rough. Compared with the plasma-nitrided coating, the CrNx coating was more uniform and denser. In the Potentiodynamic polarization test, the corrosion current densities of the plasma-nitrided coating and the CrNx coating were 0.907 and 0.312 µA·cm⁻² in the cathodic environment and 5.215 and 1.881 µA·cm⁻² in the anodic environment. A stable corrosion current density was obtained for coatings in Potentiostatic polarization test during 17 h. According to the corrosion tests results, the corrosion resistance of CrN coating was better than the plasma-nitrided coating. It was indicated that the technology process of nitriding first and then depositing Cr was better than nitriding only. The CrNx-coated 316L stainless steel under a 4 A filament current possessed a lower ICR value than that of others in the range of the measured compaction force. Based on the results presented above, the CrNx coating on the 316L stainless steel can be acted as a promising bipolar plate material for application in PEMFC.

Author Contributions: Conceptualization, S.K. and M.X.; methodology, X.Y.; software, M.X.; validation, Z.W., T.C. and X.Y.; formal analysis, M.X.; investigation, T.C.; resources, J.L.; data curation, X.Y.; writing—original draft preparation, M.X.; writing—review and editing, Z.W.; visualization, T.C.; supervision, X.Y.; project administration, J.L.; funding acquisition, S.K. All authors have read and agreed to the published version of the manuscript.

Funding: This research received no external funding.
