Abstract

It is shown that in Large–Nc QCD, two–point functions of local operators become Harmonic Sums. We comment on the properties which follow from this fact. This has led us to an aside observation concerning the zeros of the Riemann zeta–function seen from the point of view of Dispersion Relations in Quantum Theory.

Keywords: Large–Nc QCD, Dispersion Relations, Riemann’s zeta function

1. Introduction

The subject of Sum Rules in QCD was pioneered in a series of seminal papers by Shifman, Vainshtein and Zakharov (SVZ). We are celebrating in this meeting the thirty-first anniversary of these papers [1]. As shown by SVZ there are many interesting properties of Hadron Physics which in QCD are governed by two–point functions of local color singlet operators.

Here I would like to show that in large–Nc QCD, these two–point functions become simple Harmonic Sums. In full generality, an Harmonic Sum is characterized by a Base Function (in our case the dispersion relation which the two–point function in question obeys) and a Dirichlet Series

\[ \sum_{n=1}^{\infty} \lambda_n \mu_n^{-s}, \]  

where the \( \mu_n \) are called the Frequencies (the poles of the two–point function in the Minkowski region in our case) and the \( \lambda_n \) the Amplitudes (the residues of the poles).

A particular case of a Dirichlet Series is the Riemann zeta function:

\[ \zeta(s) = \sum_{n=1}^{\infty} n^{-s} = \prod_{\text{primes}(p)} \frac{1}{1 - \frac{1}{p^s}}, \quad \text{Re}(s) > 1, \]  

where \( \lambda_n = 1, \mu_n = n \). The Euler product expression in the r.h.s. extends to all prime numbers \( p \).

2. The Adler Function as an Harmonic Sum

We shall consider the Adler Function as an example to illustrate our claims. With \( \Pi(q^2) \) the vector-current correlation function, the Adler Function in the euclidean \( (Q^2 = -q^2 \geq 0) \) is given by the dispersion relation

\[ \mathcal{A}(Q^2) = \int_0^\infty dt \frac{Q^2}{(t + Q^2)^2} \frac{1}{\pi} \text{Im} \Pi(t), \]  

with a spectral function which in large–Nc QCD is an infinite sum of narrow states

\[ \frac{1}{\pi} \text{Im} \Pi(t) = \sum_{n=1}^{\infty} \gamma_n M_n^2 \delta(t - M_n^2). \]  

Setting

\[ z = \frac{M^2}{Q^2}, \quad \mu_n = \frac{M_n^2}{M^2}, \quad M^2 \equiv M_1^2, \]  

the Adler Function becomes the sum

\[ \mathcal{A}(Q^2) = \sum_{n=1}^{\infty} \gamma_n \frac{\mu_n z}{(1 + \mu_n z)^2}. \]
This is a typical Harmonic Sum which we can write as follows:

\[ \mathcal{A}(z) = \gamma \sum_{n=1}^{\infty} \lambda_n g_{\text{Adler}}(\mu_n z), \]  

(7) with

\[ \gamma \equiv \gamma_1, \quad \lambda_n = \frac{\gamma_n}{\gamma}, \]  

(8) and where the Base Function is

\[ g_{\text{Adler}}(x) = \frac{x}{(1 + x)^2}. \]  

(9)

The crucial property of Harmonic Sums is that they have a factorizable Mellin–Transform\(^3\). In our case

\[ M[\mathcal{A}(z)](s) = \gamma M[g_{\text{Adler}}(z)](s) \Sigma(s), \]  

(10) with

\[ M[g_{\text{Adler}}(z)](s) = \Gamma(1 + s)\Gamma(1 - s), \]  

(11) and \( \Sigma(s) \) the Dirichlet series in Eq. \( 1 \) with \( \mu_n \) and \( \lambda_n \) defined in Eqs. \( 5, 8 \) and \( 4 \). This implies that, in Large–\( N \), QCD, the Adler function has a simple Mellin–Barnes representation:

\[ \mathcal{A}(z) = \frac{\gamma}{2\pi i} \int_{c-i\infty}^{c+i\infty} ds \ z^{-s} \Sigma(s) \Gamma(1 + s)\Gamma(1 - s), \]  

(12) where all the Dynamics is encoded in the Dirichlet Series \( \Sigma(s) \). In this representation one can read off the asymptotic behaviours for large–\( z \) (i.e. the chiral expansion) and small–\( z \) (i.e. the short–distance expansion or OPE expansion) in a straightforward way\(^4\). The integration path in Eq. \( 12 \) lies in the so called Fundamental Strip\(^5\) which is defined by the intersection of the convergence domain of the base function, \( \text{Re}(s) \in ]-1, +1[ \) in our case, with the domain of absolute convergence of the Dirichlet Series \( \Sigma(s) \).

The remarkable property of the representation in Eq. \( 12 \) is that the dependence in \( Q^2 \) (\( z = \frac{M^2}{\alpha^2} \)) is now completely factorized from the details of the spectrum, which are in \( \Sigma(s) \). Notice that this factorization is valid regardless of the comparative sizes of the masses (frequencies) in the physical spectrum versus the value of \( Q^2 \). In fact once \( \gamma \) and \( M^2 \), the parameters of the lowest state in the spectrum are fixed\(^6\), the underlying Physics is entirely governed by the numerical series \( \Sigma(s) \). One could imagine a situation, less ambitious than solving Large–\( N \), QCD, where one may be able to calculate just the regularities which fix Dirichlet Series like \( \Sigma(s) \).

So far, at the phenomenological level and in the absence of a knowledge of the Dirichlet Series from first principles, one can proceed by making an ansatz based on known properties of the two–point function one is considering: the OPE at short–distances and chiral perturbation theory at long–distances. Ideas closely related to that have been discussed in the literature\(^7\). Here I will not get into the details of the applications which have been made so far but rather, as a homage to SVZ, I want to discuss what I think to be an interesting aside observation on Sum Rules.

3. The Riemann Zeros and Sum Rules

In Theoretical Physics, we often consider well known functions as models to illustrate some physical features which we would like to understand. Here I shall do the contrary, I will consider the physical framework of Dispersion Relations in Quantum Field Theory to discuss a problem in Mathematics. The problem has to do with the positions of the zeros of the Riemann zeta function defined by Eq. \( 2 \) and its analytic continuation\(^8\) which extends to all values of \( s \) except at \( s = 1 \) where it has a simple pole with residue 1.

The interesting object for our purposes is the logarithmic derivative of the Riemann zeta function which, using the Euler product expression in Eq. \( 2 \) can be written as a Dirichlet Series:

\[ \frac{\zeta'(s)}{\zeta(s)} = \sum_{\text{primes } p} \log(p) \sum_{k=1}^{\infty} p^{-ks} = \sum_{n=1}^{\text{Dirichlet Series}} \Lambda(n) n^{-s}, \quad \text{Re}(s) > 1, \]  

(13) where the \( \Lambda(n) \) (\( n \) integer) are the so called Von Mangoldt Amplitudes:

\[ \Lambda(n) = \begin{cases} \log(p), & \text{if } n = p^k \\ 0, & \text{otherwise} \end{cases} \]  

(14)

\(^3\)The Mellin transform of a function \( F(z) \): \( M[F(z)] \), is defined by the integral \( M[F(z)] = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} ds \ z^{-s} F(z) \), in the domain of \( s \) where the integral exists.

\(^4\)Applications of this property of the Mellin–Barnes representation in QED and QCD have been recently discussed in refs. \( 3, 5 \) and references therein.

\(^5\)Notice that \( \gamma \) is related to the electronic width of the lowest vector state: \( \gamma = \frac{G_F m^2}{2\pi^2} \Gamma_{\mu^+\mu^-} e^2 \).

\(^6\)Some relevant references are \( 2, 3 \). This is, however, a very incomplete list and I apologize for omissions.

\(^7\)For a nice elementary treatment of the Riemann zeta function see e.g. refs. \( 14, 15 \).
The poles at the point of view of QCD, this spectral function can only

be considered, at best, as a toy model of large–$N_c$, perhaps as a toy model of duality violations. What seems interesting to me, however, is the fact that such an abstract mathematical question as the RH can be phrased, as we shall see below, in terms of the language familiar to physicists working in Quantum Field Theory.

Let us call $\Pi_{\text{VonM}}(q^2)$ the two–point function which has as an imaginary part the Von Mangoldt spectral function in Eq. (16). The function $\Pi_{\text{VonM}}(q^2)$ obeys then a dispersion relation modulo a subtraction polynomial which is fixed by the requirement that the Taylor expansion at the origin $Q^2 = 0$ be well defined. The fact that the Von Mangoldt Dirichlet series in Eq. (13) is defined for Re$(s) > 1$ requires the number of subtractions to be three. They can be removed by taking three derivatives in the dispersion relation. This defines a function $\mathcal{P}_{\text{VonM}}(z)$ in the euclidean $(z = \frac{M^2}{Q^2})$, the analog of the Adler function in Eq. (3).

$$\mathcal{P}_{\text{VonM}}(z) = \int_0^\infty dt \frac{Q^2}{(t + Q^2)^2} \frac{1}{\pi} \text{Im} \Pi_{\text{VonM}}(t) \tag{17}$$

with the corresponding Mellin–Barnes representation

$$c = \text{Re}(s) \in \{1 + 1, +2\}$$

$$\mathcal{P}_{\text{VonM}}(z) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} ds \ z^{-s} \Sigma_{\text{VonM}}(s) \Gamma(s + 1) \Gamma(2 - s), \tag{19}$$

where $\Sigma_{\text{VonM}}(s)$ is given in Eq. (15). Everything is explicitly known in this representation and we can now apply the Inverse Mapping Theorem of ref. [3] to compute the asymptotic behaviour of $\mathcal{P}_{\text{VonM}}(z)$.

The interesting expansion is the short–distance expansion corresponding to large–$Q^2$ (small–$z$). This expansion is governed by the singularities at the left of the fundamental strip i.e. $s \leq 1$. The singularities at $s = -1, -2, -3, \ldots$ generated by the $\Gamma(s + 1)$ factor in the integrand and by the poles in $\Sigma_{\text{VonM}}(s)$ at $s = -2, -4, -6, \ldots$ corresponding to the trivial zeros of $\zeta(s)$ give rise to odd powers of

$$O\left(\frac{M^2}{Q^2}\right)^{2n+1}, \quad n = 0, 1, 2, 3 \ldots, \tag{20}$$

as well as to even powers ($n = 1, 2, 3 \ldots$) of

$$O\left(\frac{M^2}{Q^2}\right)^{2n} \log \frac{Q^2}{M^2}, \quad O\left(\frac{M^2}{Q^2}\right)^{2n}. \tag{21}$$

---

A plot of the Von Mangoldt amplitudes for the first hundred integers is shown in Fig. 1. In fact, there exists an explicit expression for the analytic continuation of the Dirichlet series in Eq. (13) which follows from Hadamard’s product formula for $\zeta(s)$ [15]:

$$\Sigma_{\text{VonM}}(s) \equiv -\frac{\zeta'(s)}{\zeta(s)} = \log \frac{1}{2\pi} + \frac{s}{s-1}

+ \sum_{n=1}^{\infty} \frac{s}{2n(s+2n)} - \sum_{\rho} \frac{s}{\rho(s-\rho)}. \tag{15}$$

The poles at $s = -2, -4 - 6 \cdots$ correspond to the trivial zeros of $\zeta(s)$ and the poles at $s = \rho$ to all the remaining zeros. The non–trivial zeros satisfy $0 < \text{Re}(\rho) < 1$, and because of the Symmetry Relation $s \rightarrow 1 - s$, they must be located symmetrically relative to the vertical line Re$(s) = 1/2$, the so called critical line. The famous Riemann Hypothesis (RH) states that all the non–trivial zeros have Re$(s) = 1/2$. Numerically, all the non–trivial zeros which have been evaluated so far do indeed satisfy the RH.

The question we want to discuss: What are the properties of a Large–$N_c$ QCD–like Green’s function which has as a spectral function the one associated to the Von Mangoldt Dirichlet Series i.e.,

$$\frac{1}{\pi} \text{Im} \Pi_{\text{VonM}}(t) = \sum_{n=1}^{\infty} \Lambda(n) n M^2 \delta(t - n M^2), \tag{16}$$

with the amplitudes $\Lambda(n)$ plotted in Fig. 1 replacing now the $\gamma_c$–couplings in the Adler spectral function ?

I wish to clarify the meaning of this question. From the point of view of QCD, this spectral function can only

![Fig. 1 The Von Mangoldt values $\Lambda(n)$ for the first 100 integers. The upper curve corresponds to integer values coinciding with a prime number. The background points correspond to integers which are more than a power of a prime number. They appear as successive horizontal points as we increase $n$.](image-url)
These terms are rather analogous to the usual power terms which originate in the OPE in Quantum Field Theory. The leading singularity at \( s = 1 \) gives rise to the leading asymptotic behaviour for \( Q^2 \) large, which is:

\[
\frac{1}{s - 1} \Rightarrow \Gamma(2)\Gamma(2)\varepsilon^{-1} = \frac{Q^2}{M^2},
\]

which appears in pairs of \( O\left(\frac{Q^2}{M^2}\right) \) and \( O\left(\frac{Q^2}{M^2}\right)^{-1} \), modulated by an oscillating behaviour in \( Q^2 \). In the particular case where \( \rho = 1/2 \pm i \eta \), i.e. for the zeros satisfying the RH, these terms collapse to a unique non–power behaviour of \( O\left(\sqrt{\frac{Q^2}{M^2}}\right) \):

\[
\frac{-1}{s - \left(\frac{1}{2} + i \eta\right)} + \frac{-1}{s - \left(\frac{1}{2} - i \eta\right)} \Rightarrow
- \left(\frac{Q^2 - 1 + 4\eta^2}{2M^2}\right) \cos\left(\eta \log \frac{M^2}{Q^2}\right),
\]

modulated by oscillating \( \cos\left(\eta \log \frac{M^2}{Q^2}\right) \) factors, one for each value of \( \eta \) along the critical line of zeros, with amplitudes \( \frac{1 + 4\eta^2}{2 \cos \pi \eta} \) which decay exponentially for \( \eta \) large.

**We therefore conclude:** The Riemann Hypothesis is equivalent to the existence of a unique type of non–power terms of \( O\left(\sqrt{\frac{Q^2}{M^2}}\right) \) in the short–distance expansion of the two–point function associated to the Von Mangoldt spectral function in Eq. (16).

4. Quantum Mechanics Sum Rules

It is perhaps helpful to discuss the previous considerations within a more general Statistical Mechanics Framework. My discussion will be limited to Hamiltonians \( \mathcal{H} \) with no explicit time dependence.

The probability transition amplitude in Quantum Mechanics is defined as

\[
\langle q_f, t_f | q_i, t_i \rangle = \langle q_f | e^{-\beta \mathcal{H}(t_f - t_i)} | q_i \rangle.
\]

The evolution in imaginary time leads to a Statistical Mechanics interpretation which is characterized by the Partition Function

\[
\mathcal{Z} = \text{Tr} \exp -\beta \mathcal{H}.
\]

With \( t_f - t_i = -i \beta \), we then have the spectral representation:

\[
\langle q_f | e^{-\beta \mathcal{H}} | q_i \rangle = \sum_n e^{-\beta E_n} \langle q_f | \Psi_n(q_i) \rangle \Psi_n(q_f).
\]

In particular, the \( \lim \beta \to \infty \); i.e., \( T \to 0 \), \( \beta = \frac{1}{T} \), is governed by the ground state contribution:

\[
\lim_{\beta \to \infty} \langle q_f | e^{-\beta \mathcal{H}} | q_i \rangle \approx e^{-\beta E_0} \Psi_0(q_i) \Psi_0^*(q_f).
\]

In general:

\[
E_0 = \lim_{\beta \to +\infty} \frac{-1}{\beta} \log \text{Tr} e^{-\beta \mathcal{H}}.
\]

The following quantity

\[
\mathcal{M}(\beta) = \langle q_f = 0 | e^{-\beta \mathcal{H}} | q_i = 0 \rangle = \sum_n |\Psi_n(0)|^2 \exp [-\beta E_n].
\]

is of special interest to us because it provides the Quantum Mechanics framework to discuss Riemann zeros and Sum Rules. The relevant Hamiltonian is one with levels

\[
E_n = nE_0,
\]

and wave functions at the origin

\[
|\Psi_n(0)|^2 = \Lambda(n),
\]

i.e. the Von Mangoldt amplitudes define in Eq. (14).

The relevant Mellin–Barnes representation is then

\[
\mathcal{M}_{\text{VonM}}(\beta) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} ds (\beta E_0)^{-s} \mathcal{V}_{\text{VonM}}(s) \Gamma(s),
\]

with a fundamental strip defined now by the interval \( c = \text{Re}(s) \in ]1 + \infty[ \) and \( \mathcal{V}_{\text{VonM}}(s) \) the same expression as in Eq. (15). The inverse mapping theorem applied to this formula gives us the expansion at small \( \beta \); i.e. the
expansion at high temperature ($\beta = \frac{1}{T}$):

$$
\mathcal{M}_{\text{VanM}}(\beta) \sim \frac{1}{\beta \to 0} \beta E_0
$$

$$
- \frac{1}{\sqrt{\beta E_0}} \sum_{\eta} \left[ \Gamma(1/2 + i\eta)e^{i\eta \log(\beta E_0)} + \text{c.c.} \right] + \log \frac{1}{4\pi}
$$

$$
+ \beta E_0 \left( \log(8\pi) - \frac{1}{2} + \sum_{\rho} \frac{1}{\rho(1 + \rho)} \right)
$$

$$
+ (\beta E_0)^2 \left[ \frac{1}{2} \log \frac{\beta E_0}{4\pi} - \frac{1}{2} \left( \frac{5}{6} - \gamma_E \right) \right]
$$

$$
- \sum_{\rho} \frac{1}{\rho(2 + \rho)} + O\left[(\beta E_0)^3\right].
$$

(34)

In this expression the leading behaviour in the first line is the one associated to the trivial singularity at $s = 1$, while the second line gives the asymptotic behaviour reflected by the non–trivial zeros located at $s = 1/2$.

The Riemann Hypothesis implies that these are the only possible non–power terms in the expansion. A constant term as well as odd power terms in ($\beta E_0$) are generated because of the $\Gamma(s)$ factor in Eq. 33 with coefficients which, except for the constant term, depend on the location of the non–trivial zeros (the $\rho$’s). The trivial singularities at $s = -2n$ generate powers in ($\beta E_0$)$^{2n}$ modulated by a $\log(\beta E_0)$ factor and powers of ($\beta E_0$)$^{2n}$. The latter are modulated by coefficients which also depend on the positions of the non–trivial zeros (the $\rho$’s).

An interesting question which we are investigating at present [16] is: can one reconstruct the equivalent potential which produces a spectrum of discrete levels $E_n = nE_0$ with the corresponding wave functions at the origin known in modulus $|\Psi_n(0)|^2 = \Lambda(n)$?

Acknowledgements

I wish to dedicate this written version of my talk to my friend and collaborator Joaquim Prades. Ximo courageously attended the Montpellier Conference, but he died a few weeks later. Many of us are missing him a lot.

I would also like to thank David Greynat and Josep Taron for useful discussions.
