Abstract

N\(^6\)-methyladenosine (m\(^6\)A) is a prevalent RNA methylation modification involved in several biological processes. Hundreds or thousands of m\(^6\)A sites identified from different species using high-throughput experiments provides a rich resource to construct in-silico approaches for identifying m\(^6\)A sites. The existing m\(^6\)A predictors are developed using conventional machine-learning (ML) algorithms and most are species-centric. In this paper, we develop a novel cross-species deep-learning classifier based on bidirectional Gated Recurrent Unit (BGRU) for the prediction of m\(^6\)A sites. In comparison with conventional ML approaches, BGRU achieves outstanding performance for the Mammalia dataset that contains over fifty thousand m\(^6\)A sites but inferior for the Saccharomyces cerevisiae dataset that covers around a thousand positives. The accuracy of BGRU is sensitive to the data size and the sensitivity is compensated by the integration of a random forest classifier with a novel encoding of enhanced nucleic acid content. The integrated approach dubbed as BGRU-based Ensemble RNA Methylation site Predictor (BERMP) has competitive performance in both cross-validation test and independent test. BERMP also outperforms existing m\(^6\)A predictors for different species. Therefore, BERMP is a novel multi-species tool for identifying m\(^6\)A sites with high confidence. This classifier is freely available at http://www.bioinfogo.org/bermp.

Key words: Deep learning; Recurrent neural network; bidirectional Gated Recurrent Unit; N\(^6\)-methyladenosine; Random forest

Introduction

N\(^6\)-methyladenosine (m\(^6\)A), the methylation modification on the nitrogen at the sixth position of the adenosine base, is abundant post-transcriptional modification and found from bacteria to Homo sapiens [1, 2]. Recent studies have indicated that m\(^6\)A is involved in numerous biological processes, e.g. protein translation and localization [3], mRNA splicing and stability [4]. As m\(^6\)A is non-randomly distributed in the genome [5], the identification of m\(^6\)A sites on a large scale from transcriptome allows for the understanding their biological functions.

The methylated RNA immunoprecipitation sequencing techniques such as MeRIP-seq or m\(^6\)A-seq [6, 7] have been developed for the identification of m\(^6\)A sites on a genome-wide scale from several species, i.e. Saccharomyces cerevisiae [5], Arabidopsis thaliana [8], Mus musculus [9], and Homo sapiens [9]. It is reported that m\(^6\)A peaks from both Mus musculus and Homo sapiens have a consensus motif DRACH (where D = A, G or U; R = A or G; H = A, C or U) [9], whereas those from Saccharomyces cerevisiae have the motif RGAC [5] and those from Arabidopsis thaliana have RRACH [10]. Although these motifs are
different, they share the pattern GAC, suggesting evolutionary conservation of m\(^6\)A-containing sequences. The experimental approaches have made outstanding contributions to systematic analysis of m\(^6\)A modification, but they are costly and time-consuming. It is necessary to develop computational approach for predicting m\(^6\)A sites.

A few predictors have been developed to identify m\(^6\)A sites based on high-resolution experimental data (See Table S1 for summary of the methods). They are based on two conventional machine-learning (ML) algorithms, i.e. Support Vector Machine (SVM) and Random Forest (RF), with different combinations of three types of features that are physical-chemical, sequential and structural features. Most of the predictors are species-centric (e.g. Arabidopsis thaliana, Saccharomyces cerevisiae and mammals), whereas only the approach RAM-NPPS covers all the species. As the numbers of experimentally identified m\(^6\)A sites from different species range widely (e.g. about 1,000 sites for Saccharomyces cerevisiae, 2,500 sites for Arabidopsis thaliana, and over 50,000 sites for Mammalia), it seems difficult to develop a cross-species predictor with high accuracy. Indeed, in comparison with species-specific classifiers, RAM-NPPS has better performance for the species with a small amount of identified m\(^6\)A sites (e.g. Saccharomyces cerevisiae) but seems unsatisfactory for mammals with enormous m\(^6\)A sites [11].

In addition to traditional ML methods, deep learning (DL) has become a popular and powerful tool because it provides multiple-layer networks and non-linear mapping operations to detect potential complex patterns in a data-driven manner. DL approaches have demonstrated superior performances to ML methods for the solution of several prediction problems, such as RNA splicing [12], protein structure [13], and protein modification [14]. However DL has not been applied to the prediction of m\(^6\)A sites. In this study, we constructed and compared two DL classifiers for the multi-species prediction of m\(^6\)A sites: one based on a unidirectional Gated Recurrent Unit (UGRU) with a word embedding approach and the other based on a bidirectional GRU (BGRU). BGRU outperformed UGRU for both cross-validation and independent test datasets across the species. In comparison with the conventional ML classifiers, the DL classifiers were superior for the species with the large training datasets but inferior for the species with the small datasets. To compensate for the poor efficiency of DL classifiers for small datasets, we developed a BGRU-based Ensemble RNA Methylation site Predictor (BERMP) by integrating BGRU and a Random Forest classifier with a novel encoding of enhanced nucleic acid content (ENAC). BERMP performed better than individual components and the classifiers using other feature encodings. Additionally, BERMP compared favorably to existing m\(^6\)A prediction approaches for different species. Overall, BERMP is a novel multi-species tool for identifying m\(^6\)A sites with high confidence.

**Materials and Methods**

**Dataset construction**

Two prediction modes were constructed in this study: full transcript mode and mature mRNA mode [15]. The former uses the whole DNA sequences as its input while the later uses the mature mRNA sequences. The two modes were employed for mammalian datasets, whereas the mRNA mode only was used for the datasets of Saccharomyces cerevisiae and Arabidopsis thaliana.

Figure S1 shows dataset flowcharts for three species. All the datasets are derived from previous publications. Generally, we separated the dataset into five groups of which four were used for training and the rest was employed for independent test. Specifically, for Mammalian datasets [15], we randomly selected four-fifths of the total samples for training and the remaining one-fifth for independent testing (Figure S1A). For Saccharomyces cerevisiae datasets [16], we randomly selected 2200 samples for training, and the remaining 414 for independent testing (Figure S1B). For Arabidopsis thaliana datasets [17], the 4200 samples were randomly selected for training, and the remaining 836 for independent testing (Figure S1C). Each training set was further used for five-fold or ten-fold cross validation (Figure S1). For instance, the training set of 2200 samples from Saccharomyces cerevisiae were divided into 10 groups, of which nine (1980) were used for training and the rest (220) was used for validation. The data processing flows for Arabidopsis thaliana and Mammalia excerpted from the previous studies (Figure S1A&C) [15, 17]. The cross-validation and independent test datasets are available at http://www.bioinfogo.org/bermp/download.php.

**Feature encodings**

m\(^6\)A/non-m\(^6\)A containing sequence fragments with certain length, where the m\(^6\)A/non-m\(^6\)A sites was located in the center, were extracted from DNA or mRNA sequences. If the m\(^6\)A/non-m\(^6\)A sites appeared at one terminal of the sequence, the gap symbol ‘-’ was added accordingly to the corresponding positions to ensure that the sequence length was same for all the fragments. The encoding schemes were described below.
Enhanced Nucleic Acid Composition (ENAC) encoding

Nucleic Acid Composition (NAC) reflects the frequency of the four types of nucleotides (i.e., A, G, C, U/T) surrounding the m^6A sites in the sequence fragments with the window size W. Based on the NAC encoding, we designed an ENAC encoding scheme in which the frequency of the nucleic acids was calculated in the window continuously sliding from the N- to C-terminal of each RNA fragment in the dataset. Given the size of sliding window S, a Wnt window corresponds to (W-S+1) sliding windows and its feature vector dimension of the ENAC encoding is (W-S+1)*4 (Figure S2). We searched for the optimized W and S values through the grid search approach. The value of W ranged from 51 to 101 with an interval of 10 and the value of S ranged from 1 to 14 with an interval of 2. The optimized W and S values corresponded to the best performance based on five-fold or ten-fold cross-validation, which was listed in Table S2, S3, S4, S5.

Construction of ENAC-encoding RF classifier

The RF algorithm, as a traditional ML methodology, is widely used in a variety of bioinformatics studies with effective performance. It integrates multiple decision trees and chooses the classification with the most votes from the trees. Each tree depends on the values of a random vector sampled independently with the same distribution for all trees in the forest. The framework of the ENAC-based RF classifier was shown in Figure 1, where the number of trees was set 300. This classifier was developed based on the Python module "sklearn".

Figure 1. The framework of BERMP. BERMP covered three species (i.e., Mammalia, Saccharomyces cerevisiae, Arabidopsis thaliana) with two prediction modes (i.e. full transcript mode and mature mRNA mode). After the selection of a specific species and mode, the query sequences, the query sequences were analyzed and consensus motifs were extracted with flanking nucleic acids and submitted to the random forest (RF) based classifier with ENAC encoding (left) and the bidirectional GRU-based deep learning classifier with word embedding (right). The prediction scores from both classifiers were integrated through logistical regression approach and finally the final prediction score were outputted.
Two GRU-based DL classifiers

Both the unidirectional GRU (UGRU)-based classifier and the bidirectional GRU (BGRU)-based DL classifier included five layers (Figure 1), which were detailed as follows:

(i) Input layer: A sequence of nucleotides with the optimized size (Table S6) were inputted as categorical features.
(ii) Embedding layer: each nucleotide (including ‘-’) was converted to a three-dimensional word vector for the representation of nucleotide properties according to its relative position in the sequence.
(iii) Recurrent layer: It included a bidirectional GRU block for the BGRU-based classifier that contained two GRUs each of which had 64 units, whereas it covered a unidirectional GRU block that had 64 units for the UGRU-based classifier.
(iv) Fully connected layer: 64 neuron units were established in which the rectified linear unit (ReLU) was chosen as its activation function.
(v) Output layer: One neuron unit activated using the “sigmoid” function outputted the possibility of the m6A modification. The sequence was predicted as positive if the possibility was larger than a specified threshold.

During the network training, the Adam [18] algorithm was employed to optimize the categorical cross entropy loss function. The dropout [19] rate of neurons was 20% between different layers to prevent overfitting. Meanwhile, the batch size was 1024 to guarantee a high rate of convergence. The total training process contained 1000 epochs to ensure that the loss function value was converged. The entire model was implemented by Tensorflow [20].

Integration of the classifiers

The outputs of the individual classifiers were integrated to calculate the prediction score $S$ of BERMP through the following logistic regression approach:

$$\log\left(\frac{S}{1-S}\right) = \sum_{i=1}^{2} w_i C_i + b$$

The weight $w_i$ of each classifier output $C_i$ and the bias $b$ were obtained using the regression process, with the final score $S$ denoting the confidence level of the central adenosine to be methylated. The weight $w_i$ and bias $b$ were trained and tested in a ten-fold cross-validation using the prediction outputs from the bidirectional GRU (BGRU)-based DL classifier and the ENAC-based RF classifier. The logistic model was based on the ‘glm’ function in the R package (http://www.r-project.org/).

Performance assessment of the predictors

The performance of each predictor was assessed through both cross-validation and independent tests. We used Sensitivity ($S_n$), Specificity ($S_p$), Accuracy ($A_c$) and Matthews Correlation Coefficient (MCC) to measure the predictor’s performance at certain thresholds. They are defined as:

$$A_c = \frac{TP + TN}{TP + FN + TN + FP}$$

(2)

$$S_n = \frac{TP}{TP + FN}$$

(3)

$$S_p = \frac{TN}{TN + FP}$$

(4)

$$MCC = \frac{TP \times TN - FP \times FN}{\sqrt{(TP + FN) \times (TP + FP) \times (TN + FN) \times (TN + FP)}}$$

(5)

Where TP, FP, TN and FN each represent the true positive, false positive, false negative and true negative predictions, respectively. We also plotted the receiver-operating-characteristic (ROC) curves for the predictors and calculated the area under ROC curve (AUC) to evaluate the overall performance of the predictors. The area under ROC curve with <10% false positive rate (AUC01) was considered because it reflects the performance of the predictor in a low false positive rate, which is significant in practical application.

Results and Discussion

The ENAC encoding performed best in the comparison of different feature encodings

The computational approaches for predictions of m^6A sites are generally based on different ML methods combined with various pre-defined features. We reason that although the accuracy of a prediction approach is affected by the selection of the ML method, the major determinant likely comes from the encoding schemes. Accordingly, we constructed RF-based predictors with different common encoding schemes to evaluate these encodings. We selected three common features used in the state-of-the-art m^6A predictors, i.e. Kmer, K-spaced nucleotide pair frequencies (KSNPF) and Pseudo dinucleotide composition (PseDNC) (Table S1). Additionally, we designed a novel encoding of Enhanced NAC (ENAC) in which the frequency of the nucleic acids was counted in the window continuously sliding from the N- to C-terminal of the RNA sequence (See Methods for detail). Among these encoding schemes, the ENAC encoding performed the best in the prediction of m^6A sites for both cross-validation and
independent tests for *Saccharomyces cerevisiae*, mammalian full transcript and mRNA datasets, respectively (Figure 2A&C, Figure S3A, Table 1&S7). As performance at a low false positive rate is crucial in practical prediction applications, we estimated the predictors using AUC01 where specificity was determined as >90%. ENAC still demonstrated the best performance via cross-validation and independent tests for these species (Figure 2B&D, Figure S3B, Table 1&S7).

**The bidirectional GRU-based DL approach with word embedding demonstrated superior performance**

The general PTM prediction approaches are based on traditional ML algorithms where pre-defined features are determined. Recently, DL approaches have been reported to outperform traditional ML methods in the field of bioinformatics, such as predictions of protein modifications [14, 21]. In this study, we constructed two DL classifiers: a unidirectional GRU (UGRU)-based RNN classifier...
with word embedding and a bidirectional GRU (BGRU)-based counterpart (Figure 1; See Methods for detail). BGRU had larger AUC or AUC01 values than UGRU for all the three species (P<0.03, paired student’s t-test), suggesting that the complex network architecture of BGRU is more suitable for the m6A prediction (Figure 2, Figure S3&S5, Table 1&S7). The further comparison between BGRU and the traditional ML classifiers showed that BGRU performed better for the mammalian full transcript and mRNA datasets but the reverse was true for the yeast dataset (Figure 2, Figure S3, Table 1&S7). Because the sizes of the mammalian datasets are over 50 times larger than that of the yeast dataset, we hypothesized that BGRU is more sensitive to the size of training data. To test it, we calculated the performances of BGRU and the ML representative RFENAC that were constructed separately using all (>550,000), one-fifth (110,000), one-tenth (55,000) and one-fiftieth (11,000) of the mammalian datasets with five-fold cross-validation (Figure 3&S4). Indeed, BGRU has larger AUC values than RFENAC for larger-sized data but not for smaller-sized data, although the overall performances of both approaches increased with the size of the training dataset (Figure 3&s4A). A similar observation was made for the comparison of AUC01 values (Figure 3B&S4B). In summary, BGRU is advantageous to the m6A prediction when trained using the large-scale data.

Establishment of the BERMP framework by the combination of BGRU and the ENAC-encoding RF classifier

According to the comparisons above, BGRU showed the better performance for the mammalian datasets whereas RFENAC was superior for the yeast dataset. As the combination of different classifiers have potential complementary effects on the better achievement, we explored whether an integration of the two classifiers could be more robust or perform better for the cross-species prediction. Accordingly, we developed BERMP that integrated BGRU and RFENAC through the logistic regression approach (Figure 1). BERMP achieved larger AUC01 values than BGRU for mammals (P = 1.0x10-4 for the mRNA mode; P = 3.8x10-3 for the full transcript mode; paired student’s t test) and had larger AUC values than RFENAC for yeast (P = 2.0 x10-4, paired student’s t test) via cross-validation (Figure 2, Table 1). The similar observations were made for the independent tests (Table S7).

We also evaluated BERMP for Arabidopsis thaliana by comparing it with other classifiers described above. All these classifiers had outstanding performances with AUC>0.89 and AUC01>0.05, compared with their performances for other species (Figure S5, Table 1&S7). In these classifiers, BERMP, RFKmer and BGRU had similar AUC and AUC01 values and outperformed others via cross-validation (Figure S5). Therefore, BERMP is a competitive classifier for this species (Table 1&S7).

Comparison of BERMP with published m6A prediction tools

We compared BERMP with the reported m6A predictors for three species, i.e. the Saccharomyces cerevisiae, Arabidopsis thaliana and Mammalia, respectively. As a few predictors have been developed for different species, we selected representatives for each species that were documented with good performances, i.e. SRAMP [15] for Mammalia, RFAtM6A [17] for Arabidopsis thaliana, pRNAm-PC
Table 1. Prediction results of different classifiers via cross validation.

| Species | Classifiers | Acc1 | Sn1 | Sp1 | MCC | AUC | AUC0.1 |
|---------|-------------|------|-----|-----|-----|-----|-------|
| Mammals full transcript | RF | 86.13 | 47.12 | 90.02 | 0.314 | 0.806 | 0.0340 |
| | RFkmer | 85.39 | 37.33 | 90.18 | 0.241 | 0.769 | 0.0205 |
| | RFSeq | 85.39 | 34.45 | 90.46 | 0.222 | 0.769 | 0.0219 |
| | RF-kmer | 85.17 | 30.70 | 90.60 | 0.193 | 0.727 | 0.0204 |
| | UGRU | 87.48 | 62.21 | 90.00 | 0.423 | 0.885 | 0.0403 |

| | BGRU | 56.86 | 23.64 | 90.09 | 0.184 | 0.679 | 0.0142 |
| | BERMP | 68.59 | 47.10 | 90.10 | 0.412 | 0.800 | 0.0280 |

Note: The datasets and the number of folds for cross validation were depicted in Figure S1. RF = RF classifier with the ENAC encoding, RFkmer = RF classifier with the encoding of K-spaced nucleotide pair frequencies, RFSeq = RF classifier with the encoding of Pseudo dinucleotide composition, UGRU = the unidirectional GRU-based RNN classifier with word embedding, BGRU = the bidirectional GRU-based RNN classifier with word embedding, BERMP = BGRU-based Ensemble RNA Methylation site Predictor that integrating BGRU and RF. AUC0.1 = AUC with a <10% false positive rate (i.e., specificity>90%).

Table 2. Performance comparison of SRAMP and BERMP on the independent mammalian dataset at various stringency thresholds.

| Mode | Stringency (Specificity) | SRAMP | BERMP |
|------|--------------------------|-------|-------|
| Full transcript mode | Very high (98.7%) | 25.7% | 0.373 | 29.6% | 0.421 |
| | High (93.7%) | 50.3% | 0.414 | 60.3% | 0.492 |
| | Moderate (88.1%) | 64.5% | 0.405 | 74.9% | 0.475 |
| | Low (83.0%) | 72.8% | 0.385 | 82.5% | 0.447 |
| Mature mRNA mode | Very high (99.1%) | 11.0% | 0.211 | 11.0% | 0.215 |
| | High (95.0%) | 29.6% | 0.273 | 33.5% | 0.309 |
| | Moderate (90.0%) | 44.0% | 0.293 | 48.7% | 0.325 |
| | Low (85.3%) | 54.2% | 0.294 | 58.9% | 0.325 |

Note: The very high, high, moderate and low stringency thresholds correspond to approximately 99%, 95%, 90% and 85% specificities in five-fold cross-validation tests, respectively. The same datasets were used to develop and compare both classifiers (Figure S1). The results for SRAMP excerpted from [15].

Table 3. Comparison of BERMP and other predictors on identifying m6A sites from Arabidopsis thaliana.

| Predictor | Sensitivity | Specificity | Accuracy | MCC | AUC |
|-----------|-------------|-------------|----------|-----|-----|
| BERMP     | 69.56       | 72.95       | 71.26    | 0.43 | 0.800 |
| pRNAm-PC  | 69.75       | 69.72       | 69.74    | 0.40 | 0.762 |
| M6A-HPCS  | 62.89       | 71.77       | 67.33    | 0.35 | 0.713 |
| RAM-NPPS  | 69.08       | 72.46       | 70.77    | 0.42 | 0.780 |

Note: The classifiers were based on the same dataset [16]. The results for pRNAm-PC excerpted from [22] and those for M6A-HPCS excerpted from [23]. RAM-NPPS was re-implemented and BERMP was developed using the same training dataset (Figure S1). The identical independent dataset was employed for comparison and the corresponding results were shown above (Figure S1).

Three developed classifiers (i.e. pRNAm-PC, M6A-HPCS and RAM-NPPS) were selected to compare with BERMP for Saccharomyces cerevisiae. All of them were based on the same dataset that contained 1307 positives and 1307 negatives with the length of 51 nucleic acids [16]. The specificity threshold was set around 69% for BERMP and the re-implemented RAM-NPPS to produce the sensitivity, Accuracy, MCC values. Table 3 summaries the results of the comparison of these predictors. BERMP outperformed the others with respect to sensitivity, Accuracy, MCC and AUC values. Using AUC as an example, 8.7%, 3.8% and 2.0% improvements were observed compared with M6A-HPCS, pRNAm-PC and RAM-NPPS, respectively.

Three developed classifiers (i.e. pRNAm-PC, M6A-HPCS and RAM-NPPS) were selected to compare with BERMP for Arabidopsis thaliana. Both classifiers were developed using the same dataset and evaluated based on five-fold cross-validation (Table 4). High, moderate and low specificity thresholds were selected to produce sensitivity and MCC values. BERMP performed better than RAthM6A with respect to both evaluation indexes for each threshold. In summary, BERMP was a cross-species m6A predictor with high accuracy.

In summary, BERMP was a cross-species m6A predictor with high accuracy.
method for m\textsuperscript{6}A site prediction. Although BERMP is the existing m\textsuperscript{6}A classifiers for different species.

Notably, the development of kinase classifier was developed based on hundreds of positives obtained competitive results in kinase specific phosphorylation prediction compared to traditional ML approaches [14]. To summarize, BERMP is an across-species classifier for identifying m\textsuperscript{6}A sites with high confidence. We believe that the superior performance of our DL method is mainly due to its strong capability for learning sparse representation in a self-taught manner and thus it could auto-capture the most informative features. We are also excited by the prospect that DL methods may be applied broadly to the development of classifiers for predicting other types of modification sites.
