(November 18, 2018)

A theoretical study of the coherent light scattering from disordered photonic crystal is presented. In addition to the conventional enhancement of the reflected light intensity into the backscattering direction, the so called coherent backscattering (CBS), the periodic modulation of the dielectric function in photonic crystals gives rise to a qualitatively new effect: enhancement of the reflected light intensity in directions different from the backscattering direction. These additional coherent scattering processes, dubbed here umklapp scattering (CUS), result in peaks, which are most pronounced when the incident light beam enters the sample at an angle close to the the Bragg angle. Assuming that the dielectric function modulation is weak, we study the shape of the CUS peaks for different relative lengths of the modulation-induced Bragg attenuation compared to disorder-induced mean free path. We show that when the Bragg length increases, then the CBS peak assumes its conventional shape, whereas the CUS peak rapidly diminishes in amplitude. We also study the suppression of the CUS peak upon the departure of the incident beam from Bragg resonance: we found that the diminishing of the CUS intensity is accompanied by substantial broadening. In addition, the peak becomes asymmetric.

I. INTRODUCTION

Since the first experimental observations \cite{1,2,3,4,5,6,7,8}, the phenomenon of coherent backscattering (CBS) of light from disordered media has been the subject of intense theoretical and experimental studies \cite{9,10} (see also Ref. \cite{10} for the most recent review). The underlying mechanism for the CBS was identified as interference of clockwise and counterclockwise scattering paths. This was understood already in the early works by analogy to weak localization of electrons. It has been also pointed out \cite{10} that this picture fully captures the physics of the coherent scattering only if there are no forbidden directions for the propagation of light in the absence of disorder. These forbidden directions emerge in systems with periodic spatial modulation of the dielectric function, or in other words, in photonic crystals with incomplete gaps \cite{11}. In the presence of periodicity, the enhanced scattering of light may occur not only in the backscattering direction, but in other directions as well. Roughly speaking, the additional peaks in the scattering intensity can be regarded as periodicity-induced diffraction satellites of the CBS peak. Their origin is illustrated in Fig. 1. In the presence of the periodic modulation of the dielectric function, the light wave vector is determined only up to the vector $\sigma$ of the reciprocal lattice. Hence, upon entering the medium, light with wave vector $k$ acquires a satellite component with $y$ projection of the wave vector, $k_y = k \sin \theta - \sigma$. Importantly, the same argument also applies for the coherently backscattered light with wave vector $-k$, when it propagates inside the medium on the way out, namely it also acquires a component with $y$ projection $k_y = -k \sin \theta + \sigma$ (Fig. 1). This component gives rise to a satellite of the CBS peak in the direction $\theta'$ where $\sin \theta' = (\sigma - k \sin \theta)/k$. We dub this peak in the reflected light intensity as coherent umklapp scattering (CUS). We note that the above picture is only illustrative. In reality, in addition to the process shown in Fig. 1, a variety of diffraction processes contribute to the formation of the CUS peaks. In general, the total number of the CUS peaks is determined by the number of reciprocal lattice vectors for which $| -k + \sigma | < k$.

It follows from the above qualitative picture that the magnitude of the CUS peak is governed by the ratio of the disorder-induced mean free path, $l$ (the elementary
step of light diffusion) and the characteristic length, $\xi$, of formation of the diffraction component. This formation occurs most efficiently for the incidence angles $\theta = \theta_0$, corresponding to the Bragg condition $k_y = \sigma / 2$, i.e. $\sin \theta_0 = \sigma / (2k)$. In this case $\xi$ coincides with the Bragg decay length, $L_b$, which is the decay length of evanescent wave with frequency in the middle of the photonic stop band. Away from Bragg resonance, the length $\xi$ increases resulting in suppression of the CUS peak. We note that the limiting case $L_b \rightarrow 0$ and $\theta = \theta_0$ was considered in Ref. [3]. In this case the CBS and CUS peaks are simply the mirror images of each other. In the case of photonic crystal with incomplete gap, $L_b$ is large ($kL_b \gg 1$). The question of interest is then: how do the magnitude and shape of the CUS peak depend on the parameter $\alpha$? We trace the evolution of the amplitude and width of the CUS peak with changing the parameter $\alpha$. We found that the most pronounced variation occurs within the domain $L_b \gtrsim l$ and $(\theta - \theta_0) \lesssim (kL_b)^{-1}$.

The paper is organized as follows. In Section II we review the conventional derivation of the CBS and introduce the modifications necessary to take into account the Bragg reflection in periodic structure. In Sec. III we derive analytical expressions for the CBS and CUS peaks. We trace the evolution of the amplitude and width of the CUS peak with changing the parameter $L_b/l$ and the incidence angle, $\theta$. We found that the most pronounced variation occurs within the domain $L_b \gtrsim l$ and $(\theta - \theta_0) \lesssim (kL_b)^{-1}$.

The second contribution, which is responsible for the coherent enhancement of scattered intensity, represents the sum of maximally crossed diagrams

$$U_i = \frac{4\pi e}{l^2} P(r_1, r_1') \delta(r_1 - r_2') \delta(r_1' - r_2),$$

where $P(r_1, r_1')$ is the stationary probability distribution to travel diffusively from $r$ to $r_1'$ inside the scattering medium. For the disordered medium with a boundary, this probability distribution is given by

$$P(r_1, r_1') = \frac{1}{4\pi D|r_1 - r_1'|} - \frac{1}{4\pi D|r_1 - r_1'|^2},$$

where $D = lc/3$ is the light diffusion constant and $c$ is the speed of light. The first term in Eq. (2) is a conventional propagator in the bulk medium. The second term ensures the boundary condition $P(z_0, r_1') = P(r_1, z_0) = 0$ that is imposed to describe the diffusion inside a semi-infinite medium. The point $r_1'$ is the mirror image of the point $r_1$ with respect to the trapping plane located at $z_0 \approx -0.7l$ (see Ref. [10] and references therein).

The mean incident field in the case of transversally invariant (on average) system is given by

$$\Psi_{inc}(r_1) = \exp \left( -\frac{z_1}{l \cos \theta} + ikr_1 \right),$$

where $k$ is the wave vector of the incident light ($|k| = k = \omega / c$) and $\theta$ is the angle of incidence (Fig. 1). The first term in the exponent describes the decay of the incident mean field amplitude due to scattering.

For the observation point $R$ in the far field region, the asymptotic expansion of Green’s function $G(R, r_1)$ is

$$G(R, r_1) \approx \frac{e^{ikR}}{4\pi R} \exp \left( -\frac{z_1}{l \cos \theta'} - ik'r_1 \right),$$

where $k'$ is the wave vector in the direction of observation, $|k'| = \omega / c$, and $\theta'$ is the angle between $k$ and $z$ axis.

Substitution of Eqs. (2)–(3) into Eq. (4) results in the following expression for the CBS albedo, $\alpha_0$ defined as the scattered intensity divided by the incident flux and the sample area $S$,
where $\rho$ is the component of $(r_1 - r'_1)$ parallel to the medium boundary, $\kappa = (k + k')_z$, $q = ((k + k')_x, (k + k')_y)$, and $b = (1/\cos\theta + 1/\cos\theta')$. Due to the presence of the fast oscillating exponent, $\exp(iq\rho)$, the integral in Eq. (4) is non-zero only within a narrow interval $|\theta' - \theta| \sim (k')^{-1}$ around the backscattering direction, i.e. $q = 0$. In Ref. [14] this integral was evaluated analytically for small angles $\theta$, $\theta'$. In fact, a general expression that is valid for arbitrary $\theta$, $\theta'$ can be obtained,

$$\alpha(k, k') = f(\kappa, q, b) = \frac{3}{8\pi S} \frac{1}{(k')^2 + (b + q)^2} \times \left[ b + 1 - \exp(-2qz_0) \right]. \quad (7)$$

In the next subsection we trace how the albedo (7) is modified in the presence of a weak periodic modulation of the dielectric function inside the scattering medium.

**B. Coherent scattering in the presence of a photonic crystal**

1. Modification of the wave amplitudes

Our main observation is that incomplete photonic gap affects light diffusion only weakly [14]. The probability that a certain step of the diffusive motion occurs in the forbidden direction can be estimated as $(kL_B)^{-1} \ll 1$. On the other hand, before the first and after the last scattering events the light propagates along fixed directions $\theta$ and $\theta'$. If either $\theta$ or $\theta'$ is close to the forbidden direction, then light propagation will be strongly affected resulting in a significant change in the albedo. This observation suggests that in order to calculate the coherent albedo from a photonic crystal with incomplete gap, it is sufficient to modify only the incident field amplitude in Eq. (4) and the Green function of emerging light in the Eq. (5), without changing the propagator in Eq. (4).

To model the incomplete band gap, which is narrow compared to the Bragg frequency one can keep only a single harmonic in the spatial modulation of the dielectric function,

$$\delta\varepsilon(y) = 2\delta\varepsilon \cos(\sigma y). \quad (8)$$

Here we assumed for simplicity that the direction of modulation is parallel to the boundary as shown in Fig. 1. Generalization of the results to an arbitrary angle between the boundary and the modulation wave vector is outlined in the concluding remarks.

As was pointed out above, the Bragg resonance condition has the form $k_y = \sigma/2$. For a wave propagating in a bounded medium this condition would lead to an amplitude decay $\propto \exp[-\text{Im}(k_y)y]$ in the $y$ direction, for light within the frequency range $\Delta \omega = \sigma \varepsilon \delta\varepsilon$ (the photonic stop band). However, the boundary conditions enforce a real $k_y$ value (see Fig. 1). Consequently, instead of causing a finite $\text{Im}(k_y)$, the Bragg condition manifests itself in splitting of the $z$ projection of the wave vector. This may be seen from the following relation between the components of the wave vector $\mathbf{k}$ inside the medium in the vicinity of the Bragg resonance:

$$\cos^2 \theta_B \left( \delta k_z \right)^2 - \sin^2 \theta_B \left( \delta k_y \right)^2 = \left( k\delta \varepsilon \right)^2 \quad (9)$$

where $\delta k_z = k_z - k\cos\theta_B$ and $\delta k_y = k_y - k\sin\theta_B$. The derivation of Eq. (9) is sketched in the Appendix. With $k_y = k_B = k\sin\theta_B$ fixed by the boundary conditions, Eq. (9) yields two values of $k_z$, namely $k_z = k\cos\theta_B + \Omega$ with

$$\Omega = \frac{1}{2k\cos\theta_B} \sqrt{(\sigma k \cos\theta_B \beta)^2 + (k^2\delta\varepsilon)^2} = \tan\theta_B \frac{2L_B}{\sqrt{2kL_B \cos\theta_B \beta + 1}}, \quad (10)$$

where $\beta = \theta - \theta_B$ is the deviation from the Bragg angle and $L_B = 2\sin^2\theta_B/(\sigma\delta\varepsilon)$ is the Bragg length. In the region $z > 0$, the field components with $z$ projections $k\cos\theta_B + \Omega$ and $k\cos\theta_B - \Omega$, which comprise the waves $\mathbf{k}$ and $\mathbf{k} - \sigma$ shown in Fig. 1, are coupled to each other. This leads to the following modification of Eq. (4) for $\Psi_{inc}$:

$$\Psi_{inc}(r) \approx \exp \left( -\frac{z}{l \cos\theta_B} \right) \times \left\{ C_{\Omega,\phi}(z) e^{ik_B r} + i S_{\Omega,\phi}(z) e^{i(k_B - \sigma) r} \right\}, \quad (11)$$

where the functions $C_{\Omega,\phi}(z)$ and $S_{\Omega,\phi}(z)$ are defined as

$$C_{\Omega,\phi}(z) = \cos(\Omega z) - i \cos\phi \sin(\Omega z), \quad (12)$$

$$S_{\Omega,\phi}(z) = \sin\phi \sin(\Omega z), \quad (13)$$

and $\phi$ is determined by the relation

$$\sin\phi = \frac{1}{\sqrt{(2kL_B \cos\theta_B \beta)^2 + 1}} \quad (14)$$

The first term of the field amplitude in Eq. (11) is the wave transmitted through the interface and traveling along direction close to the direction $\mathbf{k}$ of the incident wave, $(k_B)_z = k\cos\theta_B$, and $(k_B)_x y = k_{xy} = k\sin\theta$. The second term is the diffracted satellite wave. As is seen in Eq. (13), the characteristic length scale at which the latter wave is formed is $\xi = 1/\Omega$. In the limit $L_B \rightarrow \infty$ the incident wave does not change upon crossing the boundary. Indeed, the satellite wave in Eq. (11) vanishes due to the $\sin\phi$ prefactor in Eq. (13), whereas $C_{\Omega,\phi}(z)$ turns into $\exp(-ik\sin\theta_B \beta z)$ and makes up for the difference between $(k_B)_z$ and $k_z = k\cos\theta_B$.

The modification due to the Bragg scattering should be incorporated into the emerging wave propagator $G$ in a similar way. Taking into account that after the last
scattering event a wave \( \exp(i\mathbf{k}' \cdot \mathbf{r}) \) that emerges at angle \( \theta' = \theta_0 + \delta \theta \) close to the Bragg resonance also has a diffracted component inside the medium, Eq. (13) transforms into

\[
G(R, r) \approx \frac{e^{ikR}}{4\pi R} \exp \left( -\frac{z}{l \cos \theta} \right) \times \left\{ C_{\Omega', \phi'}(z) e^{-i(k_B - \sigma)r} + iS_{\Omega', \phi'}(z) e^{-i(k_B + \sigma)r} \right\},
\]

where \( \Omega' \) and \( \phi' \) are given by the same expressions (10), (13), where \( \beta \) is replaced by \( \delta \theta \). The components of the wave vector \( k_B' \) inside the medium are given by \( (k_B')_z = -k \cos \theta_0 \) and \( (k_B')_{xy} = k_{xy} = k \sin \theta' \). Expression (13) is written specifically for the observation point in the CUS direction, i.e. \( (k_B)_y > 0 \) (Fig. 1). Similarly to Eq. (11), \( G(R, r) \) represents the sum of two terms, which we dub here as C-term and S-term, respectively.

**2. CUS and CBS albedo**

Substitution of Eqs. (11) and (13) together with Eqs. (2) and (3) into Eq. (1) produces a sum of various terms with fast oscillating exponential factors. The terms with factors \( e^ {\pm i \sigma r_1} \) or \( e^ {\pm i \sigma r_1} \) average out upon integration. Since Eq. (13) is valid only in the vicinity of the Bragg resonance \( k' \approx -k + \sigma \), then nonresonant terms should be discarded. Note however, that, in addition to the oscillating terms, the product of field amplitudes (11) and propagators (13) in Eq. (1) contains now two terms proportional to \( \exp(i(k_B' + k_B - \sigma)\rho) \), which do not vanish if the outgoing light is parallel to the CUS direction. The total CUS albedo is determined by these terms and is thus given by

\[
\alpha_{\text{CUS}}(k, k') = \frac{c}{4\pi l^2 S} \int d^2 \rho dz_1 dz_1' \exp \left[ i\mathbf{q} \cdot \mathbf{r}_1 - \frac{(z_1 + z_1')}{l} \right] P(r_1, r_1') \times \left[ C_{\Omega', \phi'}(z_1) C_{\Omega, \phi}(z_1) S_{\Omega, \phi}(z_1) + S_{\Omega', \phi'}(z_1) S_{\Omega, \phi}(z_1) S_{\Omega, \phi}(z_1) \right],
\]

where \( \mathbf{q} = (k_B + k_B' - \sigma)_{xy} \).

The origin of the two terms in the coherent scattering albedo is schematically illustrated in Fig. 2. In Fig. 2a the C-component of the incident light (solid line) first experiences coherent backscattering and then is diffracted into the S component (dashed line). In Fig. 2b the C-component of the incident light is first diffracted into the S-component, the backscattering of which provides the second contribution to the CUS.

The origins of the two contributions to the CBS can be traced from Eq. (1) in a similar way (see also Fig. 2). The only technical difference between the derivations of the CBS and CUS is that for the observation point \( R \) in the CBS direction (i.e. \( k' \approx -k \)), \( \sigma \) should be added to the wave vectors in both oscillating exponents of the Green function in Eq. (13).

Substitution of the modified propagator into Eq. (1) and selection of non-vanishing resonant terms produce the following expression for the CBS albedo

\[
\alpha_{\text{CBS}}(k, k') = \frac{c}{4\pi l^2 S} \int d^2 \rho dz_1 dz_1' \exp \left[ i\mathbf{q} \cdot \mathbf{r}_1 - \frac{(z_1 + z_1')}{l} \right] P(r_1, r_1') \times \left[ C_{\Omega', \phi'}(z_1) C_{\Omega, \phi}(z_1) C_{\Omega, \phi}(z_1) + S_{\Omega', \phi'}(z_1) S_{\Omega, \phi}(z_1) S_{\Omega, \phi}(z_1) S_{\Omega, \phi}(z_1) \right],
\]
with \( q = (k_n + k'_n)_{xy} \). In the limit \( L_B \to \infty \), the diffracted waves vanish, \( S_{\Omega,\phi} \to 0 \), so that only the contribution to the albedo that survives in this limit comes from the first term of Eq. (17).

### III. RESULTS AND DISCUSSION

#### A. Analytical results

1. Expressions for CBS and CUS albedo

The additional oscillating factors \( C(z) \) and \( S(z) \) in the integrands (16), (17) compared to Eq. (15) can be formally absorbed into the decrement \( b \) by adding to it imaginary parts of the type \( i(\Omega \pm \Omega')l \). Then all the contributions to the coherent albedo can be conveniently expressed with the help of an auxiliary function, \( \tilde{f}(\kappa, p) \), defined as

\[
\alpha_{\text{CBS}}^{(1)} = \frac{\sin^2 \phi \sin^2 \phi'}{16} \left[ \tilde{f}(0, \Omega + \Omega') + \tilde{f}(0, \Omega - \Omega') \right] + \frac{1}{8} \left[ \tilde{f}(\Omega + \Omega', 0) + \tilde{f}(\Omega - \Omega', 0) \right]
\]

\[
\alpha_{\text{CBS}}^{(2)} = \frac{\sin^2 \phi \sin^2 \phi'}{16} \left[ \tilde{f}(0, \Omega + \Omega') + \tilde{f}(0, \Omega - \Omega') - \tilde{f}(\Omega + \Omega', \Omega) \right].
\]

Analogously, the CUS albedo Eq. (16) can be expressed through the function \( \tilde{f} \) in the following way

\[
\alpha_{\text{CUS}} = \frac{\sin \phi \sin \phi'}{8} \left\{ (1 + \cos \phi \cos \phi') \left[ \tilde{f}(0, \Omega - \Omega') + \tilde{f}(0, \Omega + \Omega') \right] - (1 - \cos \phi \cos \phi') \left[ \tilde{f}(0, \Omega + \Omega') + \tilde{f}(0, \Omega - \Omega') \right] \right\}.
\]

Expressions (21)–(23) are our main results. Below we analyze two limiting cases of small and large \( L_B \).

2. Limiting cases

Let us trace how the conventional CBS cone is recovered in the limit \( L_B \to \infty \). In this limit we have \( \phi, \phi' \to 0 \), so that \( \alpha_{\text{CBS}} \) and \( \alpha_{\text{CBS}}^{(2)} \) containing \( \sin \phi \) and/or \( \sin \phi' \) as prefactors, vanish. Substituting \( \phi = \phi' = 0 \) into Eq. (21) we obtain \( \alpha_{\text{CBS}}^{(1)} = f(\Omega - \Omega', q, b) \). Taking the limit \( L_B \to \infty \) in Eq. (18), we get \( (\Omega - \Omega') \to k \sin \theta_0 (\beta - \delta \theta) \). Correspondingly, \( f(\Omega - \Omega', \Omega') \) reduces to Eq. (18).

Consider now the opposite limit \( L_B / l \ll 1 \). In this limit \( \phi, \phi' \to \pi / 2 \). It follows from Eq. (18), that with decreasing \( L_B \) both \( \Omega \) and \( \Omega' \) diverge, while \( (\Omega - \Omega') \to 0 \). As a result, as can be also seen from Eq. (18), all of the terms in Eqs. (21)–(23) that contain \( \Omega, \Omega' \) or \( \Omega + \Omega' \) as at least one of the arguments, vanish. Then it is straightforward to check that both \( \alpha_{\text{CBS}} \) and \( \alpha_{\text{CUS}} \) take the form

\[
f(0, 0)/4 = f(0, q, b)/2.
\]

We thus recover the result of Ref. 13 that in the limit of strong modulation, CBS and CUS cones are the mirror images of each other. Concerning the shape of the cones, it is given by the conventional expression (18) for the coherent albedo. Concerning the peak heights, they are two times less than the height of the CBS peak in the absence of modulation.

### B. Shapes of the CBS and CUS peaks

Expressions (21)–(23) for the CBS and CUS albedo are valid only in the vicinity of the Bragg resonance.
Fig. 3. CBS (thin line) and CUS (bold line) peaks at \( L_n = 0.3l \) normalized to the CBS peak height at \( L_n/l \rightarrow \infty \) are plotted for detuning (a) \( \beta = 0 \); (b) \( |\beta| = (k l \cos \theta_B)^{-1} \); (c) \( |\beta| = 2(k l \cos \theta_B)^{-1} \). The peak maxima occurring at \( \delta \theta = \beta (\delta \theta = -\beta) \) for the CBS (CUS) are shifted to \( \delta \theta = 0 \) for convenience.

\( \theta, \theta' \approx \theta_B \). Note, however, that only in this region CUS has an appreciable amplitude. To illustrate this we plot in Fig. 3 the CBS and CUS cones for different detunings, \( \beta = \theta - \theta_B \), of the incident beam from the Bragg angle for \( L_n/l = 0.3 \). It is seen that CUS practically dies out at \( \beta \approx (2kL_n \cos \theta_B)^{-1} \ll 1 \). It is also seen that as the amplitude of the CBS peak falls off, the peak also becomes asymmetric. The behavior of the CUS and CBS peak heights with the detuning \( \beta \) is summarized in Fig. 4.

Consider now the case of exact resonance, \( \beta = 0 \). As was discussed above, the relation between the CBS and CUS peaks is governed by the dimensionless parameter \( L_n/l \). In Fig. 5 we show the heights of both peaks as functions of \( L_n/l \). It is seen that the amplitude of the CBS peak saturates already at \( L_n/l \gtrsim 2 \); at the same time, the CUS peak diminishes by an order of magnitude.

In Fig. 6 we illustrate the evolution of the CUS cone at \( \beta = 0 \) with increasing \( L_n/l \). For reference the CBS cone for \( L_n/l = 0.3 \) is also plotted in Fig. 6 (solid line). We note that, while the CUS peak keeps narrowing for \( L_n \lesssim l \), the shape of the CBS cone remains practically unchanged with \( L_n/l \).

IV. CONCLUSIONS

In this paper we have studied coherent light scattering from a disordered photonic crystal with incomplete band gaps. We have demonstrated that the crystal dielectric function periodicity gives rise to additional coherent albedo peaks in non-backscattering directions. These peaks emerge as the angle of incidence, \( \theta \), approaches the Bragg resonance, \( \theta \approx \theta_B \). For simplicity, the consideration was restricted to the case where the modulation wave vector, \( \mathbf{\sigma} \), is parallel to the crystal boundary. In this case, and under the Bragg resonance condition \( 2k l \sin \theta_B = \sigma \), the direction of the additional (CUS) peak coincides with the reflection direction, since the CUS wave vector is equal to \( \mathbf{k}' = -\mathbf{k} + \mathbf{\sigma} \). The component of \( \mathbf{k}' \) parallel to the boundary is equal to \( k'_x = -k \sin \theta + \sigma \). Then at \( \theta = \theta_B \) we have \( k'_x = k_\gamma = \sigma/2 \). It is important to note that this relation is specific for \( \mathbf{\sigma} \) parallel to the boundary (and for the wave vector of incident light lying in \( yz \) plane).

Consider now the case where \( \mathbf{\sigma} \) and the incident light wave vector still lie within \( yz \) plane, but \( \mathbf{\sigma} \) is no longer parallel to the boundary, but rather makes an angle \( \gamma \) with the \( y \) axis. In this case the Bragg condition takes the form \( 2k \sin \theta_B = \sigma \), where \( \theta_B = \sin^{-1} \left( \frac{\sigma}{2k} \right) - \gamma \).
In Eqs. (16), (17) for the CUS and CBS by \( \theta \)
amounts to the replacement of the functions \( C \) and \( S \) in Eqs. (16, 17) for the CUS and CBS by
\[
C_{\tilde{\Omega}, \tilde{\phi}} = \cos \tilde{\Omega} z - i \sin \tilde{\phi} \sin \tilde{\Omega} z, \tag{24}
\]
\[
S_{\tilde{\Omega}, \tilde{\phi}} = \left[ \frac{\cos \tilde{\theta}_B}{\cos(\tilde{\theta}_B + 2\gamma)} \right]^{1/2} \sin \tilde{\phi} \sin \tilde{\Omega} z, \tag{25}
\]
where
\[
2\tilde{\Omega} = \frac{\sin \theta_B}{L_B \cos(\theta_B + 2\gamma)} \sqrt{(2k\tilde{L}_B \cos(\theta_B + \gamma) \beta)^2 + 1}, \tag{26}
\]
is the modified splitting between the two solutions of Eq. (8) for \( k \).

The modified Bragg length in Eq. (26) is defined as \( \tilde{L}_B = L_B \sqrt{\cos \theta_B / \cos(\theta_B + 2\gamma)} \) The parameter \( \tilde{\phi} \) in Eq. (26) is still given by Eq. (14) with \( L_B \to \tilde{L}_B \).

To derive Eqs. (24), (26) it is convenient to perform a rotation of the coordinate system by the angle \( \gamma \). Then the additional factors in (25), (26) as compared to \( \gamma = 0 \) emerge due to the modification of the boundary conditions. Other steps of the derivation remain unchanged.

It is seen from Eqs. (25), (26) that the prefactors diverge at \( 2\gamma = \frac{\pi}{2} - \tilde{\theta}_B \). This divergence corresponds to the physical situation where the diffracted component of the incident light is aligned with the boundary. With regard to the coherent scattering, the condition \( 2\gamma = \frac{\pi}{2} - \tilde{\theta}_B \) manifests a crossover to a new regime.

**Fig. 5.** CBS and CUS peak heights normalized to the CBS peak height at \( L_B/l \to \infty \) plotted vs. \( L_B/l \).

It is easy to see that together with the CUS condition \( k' = -k + \sigma \) this determines the CUS direction \( \theta_{\text{CUS}} = \tilde{\theta}_B + 2\gamma \), whereas the reflection angle is \( \theta = \tilde{\theta}_B \).

This latter case can be exploited in experiments.

Generalization of our theory to the case of finite \( \gamma \) amounts to the replacement of the functions \( C \) and \( S \) in Eqs. (16, 17) for the CUS and CBS by
\[
C_{\tilde{\Omega}, \tilde{\phi}} = \cos \tilde{\Omega} z - i \sin \tilde{\phi} \sin \tilde{\Omega} z, \tag{24}
\]
\[
S_{\tilde{\Omega}, \tilde{\phi}} = \left[ \frac{\cos \tilde{\theta}_B}{\cos(\tilde{\theta}_B + 2\gamma)} \right]^{1/2} \sin \tilde{\phi} \sin \tilde{\Omega} z, \tag{25}
\]
where
\[
2\tilde{\Omega} = \frac{\sin \theta_B}{L_B \cos(\theta_B + 2\gamma)} \sqrt{(2k\tilde{L}_B \cos(\theta_B + \gamma) \beta)^2 + 1}, \tag{26}
\]
is the modified splitting between the two solutions of Eq. (8) for \( k \).

The modified Bragg length in Eq. (26) is defined as \( \tilde{L}_B = L_B \sqrt{\cos \theta_B / \cos(\theta_B + 2\gamma)} \) The parameter \( \tilde{\phi} \) in Eq. (26) is still given by Eq. (14) with \( L_B \to \tilde{L}_B \).

To derive Eqs. (24), (26) it is convenient to perform a rotation of the coordinate system by the angle \( \gamma \). Then the additional factors in (25), (26) as compared to \( \gamma = 0 \) emerge due to the modification of the boundary conditions. Other steps of the derivation remain unchanged.

It is seen from Eqs. (25), (26) that the prefactors diverge at \( 2\gamma = \frac{\pi}{2} - \tilde{\theta}_B \). This divergence corresponds to the physical situation where the diffracted component of the incident light is aligned with the boundary. With regard to the coherent scattering, the condition \( 2\gamma = \frac{\pi}{2} - \tilde{\theta}_B \) manifests a crossover to a new regime.

**Fig. 6.** Normalized CUS albedo at exact resonance, \( \beta = 0 \), shown for \( L_B = 0.3l \) (dashed line) and \( L_B = l \) (dot-dashed line). Solid line: normalized CBS albedo at \( \beta = 0 \) and \( L_B = 0.3l \).

In this regime the diffracted wave does not “fit” into the medium, so that the CUS peak is absent. Formally, for \( 2\gamma > \frac{\pi}{2} - \tilde{\theta}_B \) Eq. (8) does not have real solutions for \( k \), for small \( \beta \), which corresponds to opening of the photonic band gap in \( z \) direction. As a result, the CBS peak exhibits an anomaly in the vicinity of the Bragg condition.

We did not address in the present work the modifications of the theory caused by a difference of refraction indices on two sides of the interface. The impact of the light refraction on the CBS was intensively studied (see Ref. 10 and references therein). A non-trivial consequence of the refraction index mismatch is that in course of diffusion the light wave can “strike” the boundary at an angle exceeding the angle of total internal reflection. Basically, the CUS can be viewed as a mirror image of the CBS, hence the effect of the index mismatch on CUS is similar to that on CBS.

**APPENDIX:**

In the vicinity of the Bragg resonance, \( k_y \sim \sigma/2 \), we employ the coupled wave approach, i.e. we search for the field inside the medium with dielectric function given by Eq. (8) in the form of a sum of two waves with wave vectors \( k \) and \( k - \sigma \) and amplitudes \( A_k \) and \( A_{k-\sigma} \), respectively. Substitution of this form into the wave equation results in a following system of coupled equations for the wave amplitudes.
where we used the definition of the Bragg angle $\sin \theta_B = \sigma / (2k)$. The system (1) together with the assumption $\cos \theta \approx \cos \theta_B$ lead to Eq. (3).

It is convenient to express the modulation strength $\delta \varepsilon$ in terms of the Bragg decay length, $L_B$, given by

$$L_B = \frac{2 \sin^2 \theta_B}{\sigma \delta \varepsilon}.$$  \hspace{1cm} (2)

It is easy to see from Eq. (2) that the meaning of $L_B$ is the decay length for light of frequency $\omega = kc$ in the middle of the Bragg gap, when the medium boundary is perpendicular to the modulation direction $y$.

If the condition given in Eq. (3) is satisfied, then there exists a nontrivial solution of the system (1),

$$\lambda_{1,2} = \frac{A_{k-\sigma}}{A_k} = \frac{\cos \phi \pm 1}{\sin \phi},$$ \hspace{1cm} (3)

with $\phi$ defined by Eq. (14). The two signs in the numerator correspond to the two solutions of Eq. (1) for $k_z$. Upon matching the solution for the field amplitude with the incident wave, the resulting field can be cast in the form of Eq. (11).
