AutoNav: Evaluation and Automatization of Web Navigation Policies

Benjamin Eriksson

Chalmers University of Technology

Exploiting these vulnerabilities is effective because clients manipulate highly sensitive information, like login credentials, banking, health, and location data, on behalf of the user.

1.1 Motivation

One of the bigger classes of client-side security vulnerabilities on today’s web is cross-site scripting (XSS) [45]. An XSS vulnerability gives an attacker the power to execute JavaScript code on another website. This can be used to steal user credentials, change the behavior of the application or render the website unusable. A common approach to mitigate this problem is to let servers send extra security policies along with each HTTP response. The web browser will then enforce these policies, for example, by restricting which scripts to allow on the webpage. These security policies have been defined by the web security community as part of Content Security Policy (CSP) [63].

Navigation attacks The current CSP standard (level 2 [63]) does not address attacks via navigation. Attackers can thus freely redirect users to malicious or inappropriate websites. This type of attack can affect the confidentiality, integrity and availability of the attacked website. For confidentiality, an attacker with injection capabilities can inject the following script to leak the secret cookie.

\[
\begin{align*}
1 & <script> \\
2 & \text{window.location} = "http://evil.com/?c=\text{document.cookie};" \\
3 & </script>
\end{align*}
\]

When the script is executed the user will be sent to http://evil.com, along with their cookies, potentially allowing the attacker to take over their account. In addition to only stealing the cookie, the attacker could launch a phishing attack by designing http://evil.com to look like the attacked website. Here the user could be asked to supply more confidential information or be forced to download malicious software. The availability of the website is also compromised as every user visiting the page containing the injected script will be sent away. Note that while CSP can block scripts, an attacker could also force the user to perform a navigation by using meta tags as shown below. While not valid HTML, modern browsers will follow meta redirects in the HTML body.

\[
\begin{align*}
1 & \text{<meta http-equiv="refresh"} \\
2 & \text{content="0;URL=\"http://evil.com\""} />
\end{align*}
\]

The navigate-to directive To mitigate these problems the World Wide Web Consortium (W3C) has drafted a standard for the new CSP directive navigate-to [61]. This directive has already been implemented in Chrome [36] and Firefox [28]. A common motivation for the directive is to increase the security on websites, as well as, give advertising platforms better control over navigations in ads [40]. We illustrate this in two example scenarios: HTML/JavaScript injection and malicious advertisement.

HTML/JavaScript injection Understanding the space of navigation links on a website can improve security thanks to navigate-to. By
limiting the possible navigations, attackers will not be able to redirect users. A real-world example of where this policy would have helped is a vulnerability on blockchain.info [27]. Attackers were able to inject HTML and JavaScript into the search function on the page. This meant that a URL similar to blockchain.info/?search=<code>, which appears to point to blockchain.info, could redirect the user to another website. This is known as a reflective XSS vulnerability [48], as the code in the URL is reflected onto the page. Although blockchain.info used CSP to mitigate XSS, it was still possible to inject HTML code that forces a redirect. With the new directive, the following CSP policy can mitigate this type of attack. This policy blocks any navigation attempt to anything but self, i.e., blockchain.info.

Insecure policies or broken websites [56, 57]. To help developers use the new directive, and increase both usability and adoptability, we investigate the possibility of automatically generating navigation policies. Hence, the question: Can automatic mechanisms be used to help generate the new policy?

Performance In contrast to CSP directives like script-src, intended to whitelist lists that can be loaded by a webpage, the navigate-to directive will whitelist possible navigations. This results in already lengthy response headers becoming even larger, further increasing the overhead of security headers. This brings us to the question of performance: What are efficient methods for delivering the new policy?

1.3 Contributions

This paper is a first systematic evaluation of navigate-to. Our goal is to both initiate research on navigation security and to affect the emerging standards for navigation policies. We examine the security implications, efficiency, and the possibility of automatic generation of the new navigate-to policy.

Security The intricate connections between policies together with the growing complexity of the web results in new mechanisms becoming more challenging to incorporate into the ecosystem. This motivates the need to analyze multiple types of attackers, as well as, reexamining existing mechanisms in combination with new ones. We follow a methodology of examining the effects of navigate-to on a comprehensive range of attackers: injection [5], gadget [6], web [2] and passive network [25] attackers. By scrutinizing the full attack surface of the new directive, with respect to different types of attackers, we identify specification- and implementation-level vulnerabilities that can be exploited (Section 3). The vulnerabilities allow attackers to probe other websites to detect if users are logged in or have active shopping carts, bypass blocking mechanisms of third-party cookies, leak browsing history, and open up new methods for exfiltration. This demonstrates that the directive “breaks the web” in the sense of introducing vulnerabilities even in otherwise secure websites that do not use the directive in their policies. We present mitigations to security problems, both for web and policy developers (Section 4).

Automatization Looking ahead when the proposed mitigations are in place, our goal is to aid in the adoption of navigate-to. We develop AutoNav, an automatic mechanism for navigation policy inference (Section 5). AutoNav crawls websites and generates navigate-to policies. The goal of this mechanism is to simplify the deployment of the new directive by helping web developers and security engineers to find fitting policies for their websites. To further improve security, AutoNav can also generate origin-wide policies for the new origin policy delivery mechanism that is currently being drafted [59]. This improves security by applying the policy to the entire origin, covering pages that are easy to forget, like error pages. We implement and evaluate the mechanism by an empirical study (Section 6). In our experiments, we crawl 100 pages per domain for 10,000 domains. Based on a subset of 80 pages, AutoNav generates a policy for the remaining 20 pages. For 42% of websites, AutoNav generated a policy which fully covered the 20 pages, and at 59% 19 out the 20 pages were covered. Further investigation into the category of websites shows that shopping websites and adult websites are the easiest to cover.
Performance To evaluate the performance impact of the policy we perform an empirical study (Section 6). Based on 10,000 crawled domains from Alexa’s top 10,000, the policy will result in an overhead of 215 bytes for each HTTP response. We create simplification strategies to find a balance between security, performance and maintainability. These simplifications convert complicated policies with multiple subdomains to more manageable policies by using wildcards. For example, instead of including all language-specific subdomains from Wikipedia navigate-to *.wikipedia.com would be enough. Our simplification algorithm decreased the overhead by between 40% and 47%. Furthermore, we show that the use of an origin policy would result in an overhead of 1904 bytes in total, as opposed to per HTTP response. This is further decreased to 1004 bytes by using our simplification algorithm. A 900 byte reduction might not seem like much, but it can have a big impact on larger websites [21].

2 Background

Setting the background, we present the threat model in terms of relevant attackers. We describe CSP and how it relates to the origin policy. Finally, we explain navigation methods and how they are treated in the navigate-to directive.

2.1 Threat model

The main goal of the navigate-to directive is to give web developers control over where users can navigate from their website. The assets that need protecting include confidentiality, integrity and availability. Previous research has already shown how confidential information, such as cookies, can be exfiltrated using navigation [65]. While the new directive is a step in the right direction to address data exfiltration, Zalewski [65] points out that control over navigation is not necessarily enough. Attackers could, for example, inject HTML or JavaScript that change documents from private to public on a website like Dropbox. Forced navigation can also be used for phishing attacks by redirecting users to a similar-looking, but attacker-controlled, website.

Modern web browsers support many different methods for navigation, e.g. by clicking on a link, submitting a form, etc. These navigation methods, and the subset that the navigate-to directive is intended to apply to, are explained in Sections 2.4 and 2.5.

As mentioned above, we are interested in a comprehensive security evaluation of the impact of the directive on the entire web ecosystem. Hence, our threat model includes four types of attackers from the security literature [39]: injection, gadget, web and network attackers. In practice there is some overlap between the classes, for example, an attacker with web attacker capabilities will usually also have injection attacker capabilities. However, the best mitigation strategy might be different depending on which specific class we need to defend against. Therefore it is important to study each distinct class of attacker.

Injection attacker The injection attacker [5] is able to inject content into a website. A typical example is a user who can post content on a forum. If the user’s post contains JavaScript then that code could be executed by other users on the site, in this scenario, with the goal to force a navigation.

Gadget attacker The gadget attacker [6] is similar but more powerful as they are allowed to host code, or gadgets, on other websites. A notable example is JQuery which is a JavaScript snippet that is used by many websites. Since JavaScript do not support any isolation, these gadgets run with the same capabilities as other scripts on the website. A malicious gadget could exfiltrate information from the website it is integrated to, modify content on pages or even navigate the user away from the website.

Web attacker The web attacker [2] is able to host and configure a full website. This is especially important for advertisers who want to ensure that the landing page does not redirect to anything other than what was specified in the ad.

Passive network attacker A passive network attacker [25] can listen in on all the traffic sent from and to a client but can not decrypt HTTPS. If the traffic is not encrypted, the attacker can read passwords and session cookies being sent to the server.

Note that navigate-to is not designed to handle network attacks. Yet we pay attention to network attackers in our effort to analyze the impact of the directive on the entire web ecosystem.

2.2 CSP

CSP is intended to mitigate cross-site scripting (XSS) and other code injection attacks. The current version of CSP, level 2, is supported by all major web browsers [26]. Level 3, which includes the new navigate-to directive, is being discussed and drafted [61].

CSP protects the users by specifying which resources and scripts are allowed on a page. The web server sends the CSP policies each time a user requests a page. These policies are then enforced by the browser to, among other things, block XSS. The policy below will only allow scripts to be loaded from the current origin, still blocking any injected inline scripts. In addition, the reporting header Content-Security-Policy-Report-Only [33] can be used to report policy violations without enforcing them. These reports are sent as POST requests to the server. They can also be detected using SecurityPolicyViolationEvent in JavaScript.

```
1 Content-Security-Policy: script-src 'self'
```

2.3 Origin policy

Today, CSP headers are sent with every HTTP(S) response, which is a concern for both safety and performance [50]. For security, it is easy to forget the policy on special pages, like error pages [59]. It also harms performance because servers need to repeat the same policy for each response, even if the policy should apply to all. To address this, specifications are being drafted [59], implemented [60], and evaluated [50] to enable origin-wide policies, known as origin policies [59] or origin manifests [50]. Using an origin policy, the server only needs to include once which policies should apply to the whole origin.

2.4 Navigation

Navigations can be performed in many different ways by browsers, e.g. by clicking on a link, submitting a form or running JavaScript. Navigation methods can be split into two different categories, user-initiated or document-initiated. While navigation is defined in the Fetch [52] and HTML [4] standards, the exact methods available depend on the web browser implementation. We make an effort to summarize the most common methods in Table 1. The Automatic column shows if the navigation method can be performed automatically. This is true for all JavaScript function and, in case JavaScript is allowed, <a> and <form> tags. It is worth noting that while a web page...
cannot read a user’s browsing history, it can initiate navigation to go back or forward in the browser history. There are many .location functions in JavaScript that can navigate, e.g., window, document, parent, etc. They all use the Location object defined in the HTML standard [4]. Some functions, like window.navigate, only works in Internet Explorer [11]. The last column specifies which methods navigate-to affects.

Table 1: Navigation methods together with initiator and possibility to automatically affect.

| Method            | Initiator     | Automatic | Affected |
|-------------------|---------------|-----------|----------|
| `<a>` tag         | Document      | No JavaScript | ✓        |
| `<iframe>` tag    | Document      | With JavaScript | ✓        |
| `window`          | Document      | Yes       | ✓        |
| `window.open` [5] | Document      | Yes       | ✓        |
| `document.navigate` [11] | Document | Yes | ✓ |
| Typing the URL    | User          | No        | ✓        |
| History buttons   | User & Document | Yes     | ✓        |
| History buttons   | User          | No        | ✓        |

2.5 Navigate-to directive

The navigate-to directive gives developers the power to control the navigations a document can initiate. Document initiated navigations are discussed in Section 2.4. This directive makes it harder for attackers to inject code to redirect users from legitimate websites. For example, if an attacker manages to inject links on disney.com then Disney’s reputation is at stake if links lead to inappropriate websites. To tackle this, Disney could add the following to their CSP policy:

\[ navigate-to *.disney.com disney.com \]

This would instruct the browser to only accept navigations to subdomains of disney.com and thewaltdisneycompany.com and block all navigations to other websites. The standard also introduces the new keyword `unsafe-allow-redirects`, which allows any redirects as long as the final destination is allowed by the policy. It is deemed less safe since it does not have full control over all the sites in the redirect chain. However, it is still better than nothing in terms of limiting navigations.

The navigate-to directive is currently being standardized by W3C [61] and implemented in Chrome [36] and Firefox [28]. It is available in the current version of Chrome (version 77.0.3865), and other Chromium-based browsers like Edge and Brave, behind a flag that enables experimental features. It is also available in Firefox Nightly (Version 71.0a1) behind a flag [28].

3 Vulnerabilities

This section presents vulnerabilities and security concerns related to the navigate-to policy. These vulnerabilities are not navigation attacks, but rather vulnerabilities that become possible due to navigate-to. Except for the last vulnerability in Section 3.3.3, where we rather want to show that a small improvement to navigate-to can solve an existing problem. The policy introduces new methods for acquiring privacy-sensitive information, circumvention of security mechanism and data exfiltration. All the attacks described in this section have been tested in practice. While some of the vulnerabilities, like the data exfiltration, relies on the existence of other vulnerabilities, like content injection, the navigate-to adds a new layer to the attacks. This possibility of combining attacks shows the importance of reexamining existing ones when introducing new mechanisms.

3.1 Methodology

To systematically find vulnerabilities we distinguish vulnerabilities relating to the specification of the navigate-to directive and vulnerabilities related to its implementation. For each category, we divide the investigation of vulnerabilities pertaining to confidentiality, integrity and availability, in accordance with the CIA triad. We draw on our threat model and examine vulnerabilities with respect to injection, web, gadget, and passive network attackers. Finally, we analyze how the directive can be used to circumvent modern countermeasures, such as third-party cookie blocking.

The presentation of the vulnerabilities is ordered by our estimate of their impact, from high to low. Table 2 lists the vulnerabilities we discover together with their corresponding attacker model. Interesting to note is that resource probing and Google Search profiling can be exploited to attack websites that themselves do not use the navigate-to directive. This results in previously security websites becoming insecure.

Table 2: The uncovered vulnerabilities together with corresponding attacker model.

| Vulnerability / Attacker | Injection | Web | Gadget | Passive network |
|--------------------------|-----------|-----|--------|-----------------|
| Resource probing         | ✓         |     |        |                 |
| Google Search profiling  | ✓         |     |        |                 |
| Third-party cookie bypass| ✓         |     |        |                 |
| History sniffing         | ✓         |     |        |                 |
| Data exfiltration        | ✓         | ✓   |        |                 |
| Ads leaking data          |           | ✓   | ✓      |                 |

3.2 Specification

The following vulnerabilities are present in the specification. This means that any browser following the specification correctly will be vulnerable.

3.2.1 Resource probing In cases where web applications redirect based on sensitive resources, these resources could be probed. For example, probing for the existence of Dropbox files. The probing attacks in this section are deterministic, as opposed to other attacks that rely on timings [55]. The attacks are also general and could potentially be used on any website, not solely on advertiser platforms such as the attack presented by Venkatadri et al. [54]. A malicious website, i.e. a web attacker, can navigate a user to dropbox.com/preview/wallet.txt to detect if a user has a file named wallet.txt. If no such file exists then the user is redirected to dropbox.com/home/wallet.txt, making it possible to craft a policy which blocks /preview/ but not the redirection to /home/, like the following. Note here that we only use path-sensitivity to
block /preview/. If we are redirected, then path-sensitivity is no longer available and we only have to allow dropbox.com. The main difference compared to previous work on CSP redirections [23] is that we only need path-sensitivity for the first request, not the redirects.

By utilising invisible iframes multiple files can be checked in parallel, without the user being navigated away from the malicious website.

One specific application of resource probing that has been researched before is login detection. Previous methods [20, 32] relies on third-party cookies, which can be blocked by the user or by the proposed default SameSite policy [62]. Instead, note that a navigation to facebook.com/settings/ will redirect the user to the login page, facebook.com/login.php, if they are not authenticated, similar to Figure 1. By allowing only one of these URLs in the policy, the attacker can differentiate between a successful navigation and a blocked one. This feature makes our method more powerful and general.

We have also found that on some E-commerce websites it is possible to detect if a customer has anything in their shopping cart. This is because navigating directly to the shopping cart or checkout page sometimes redirects the user depending on the content of the cart. PrestaShop, which is an E-commerce platform used on hundreds of thousands of websites [8], does exactly this. By visiting example.com/en/order a user will be redirected to example.com/en/cart, assuming example.com uses PrestaShop.

Some of the probing attacks can leak more data if they are done in an active fashion. The PrestaShop attack can be improved to, in theory, enumerate the full cart. This is due to a Cross-Site Request Forgery (CSRF) [47] vulnerability in PrestaShop, currently being disclosed, which allows an attacker to add and remove items. Using this method an attacker can repeatedly remove items and then check if the cart is empty.

These are only a few examples we have found where redirects are based on sensitive data. We believe that many more such redirects currently exist on the web. Furthermore, navigations can bypass lax SameSite cookies, making the attack possible on sites where previous CSRF attacks were not possible.

3.2.2 Google Search profiling Google Search relies on personalized search [19], meaning that the results of a search query are based on the users’ previous interactions with Google. A recent study [24] shows that users are put into so-called “filter bubbles” by Google, resulting in varying result when searching for political terms such as “gun control” or “immigration”. A web attacker can craft a malicious website which uses the navigate-to directive together with Google’s I’m feeling lucky function to extract top results from visitors. This type of extraction attack is called cross-site search and has previously been successfully mounted against Gmail and other websites [17]. The main difference is that previous methods have relied on timing, whereas our method is fully deterministic. Castelluccia et al. [10] were also able to infer sensitive information about users based on Google Searches. However, their approach required network attacker capabilities and assumed the traffic was unencrypted, which is not the case anymore. Our attack can be mounted by anyone with the capability to set up a website.

The attacker can then use these top results from Google to infer these filter bubbles. Using the URL https://www.google.com/search?q=QUERY#btnI, Google will automatically redirect the user to the top result for term “QUERY”. Therefore the I’m feeling lucky function acts as an open redirector, which is something both OWASP [46] and Google [34] themselves warn about. It is well known that Google has this problem but so far they choose to accept the risk [1]. However, the navigate-to directive adds a new dimension to the problem as it enables attackers to infer data about users.

To exploit this the attacker can specify a report-only policy that only allows google.com, as shown below. The redirect will violate the policy and the browser will dutifully report which domain was in violation to the malicious website. The attacker can iteratively update the query to get more results. Assuming searching for “news” would return news.com, then the next query would be news-site:news.com, which excludes news.com and perhaps returns reports.com instead. Another attack vector would be other search engines using this approach to directly copy personalized search results from Google, similar to what Bing did [41].

3.2.3 Third-party cookie bypass A cookie is a piece of data that websites can save locally on users’ machines. [31] Depending on how the cookie is acquired, it will either be considered a first-party cookie or a third-party cookie. A navigation will result in first-party cookies while image request and similar results in third-party cookies.

Third-party cookies are useful for advertisers [14] as it allows them to use small tracking pixels [15] for tracking users. Modern browsers allow users to block third-party cookies or do it by default [42].

Previous work has demonstrated how Cookie Synchronization [7, 38] can be used by ad platforms to effectively break the same-origin policy. Privacy-aware users can mitigate this by blocking third-party cookies altogether. However, the navigate-to directive introduces a new method for advertisers to circumvent this by using navigations. As it requires control over the CSP headers, web attackers are the main threat. Figure 2 shows a user visiting a.io, then being forcibly navigated to track.com and acquiring a first-party cookie. Using the following policy, the redirection will be blocked, making the attack unnoticeable to the user.

3.3 Implementation

The following vulnerabilities are due to implementation decisions. We focus on Chrome’s [36] and Firefox’s [28] implementations of navigate-to.

3.3.1 History sniffing The navigate-to policy can, in some cases, be exploited by a web attacker with a malicious website to probe
which websites a user has visited. The attack uses the fact that websites using HSTS force the browser to remember and upgrade insecure connections. Previous methods exploiting this have relied on timing attacks which are now mitigated [64].

Using navigate-to, a malicious website can make a POST request to another site which uses HSTS but is not preloaded. If the site redirects based on the POST data then the attacker might be able to detect if a user has visited the site before. This is possible because if the user has visited the site before it will result in an internal redirect (HTTP 307), which keeps the POST data. Otherwise, the server will redirect (HTTP 301/302), which drops the POST data. If the server specifically performs a 307 redirect then the attack will not work. By crafting a CSP that does not allow the redirect, the attacker can differentiate between the two cases, denoted X and Y in Figure 3. This is, for example, possible using the login function on the popular social media website VK.

3.3.2 Data exfiltration and communication Previous research has shown that data exfiltration is possible in the face of CSP [49]. The usage of forms and links to exfiltrate data has also been studied [65]. However, the navigate-to policy introduces an improved method for exfiltration, and two-way communication, based on JavaScript together with navigation. This works in Chrome, but not Firefox, as Chrome does not unload the page for navigate-to violations.

Consider a website using connect-src 'none' and frame-src 'none' to limit external loads as much as possible. The connect-src directive protects against some exfiltration methods including XHR, fetch and <a ping>, while frame-src will block exfiltration to iframes. Assume the website uses unsafe-allow-redirects followed by a list of allowed URLs. Note here that we show that unsafe has implications beyond the scope of restricting navigation. An attacker capable of injecting JavaScript, i.e. either an injection or gadget attacker, can now use window.location, as shown in the listing below, to exfiltrate arbitrary data. Each navigation request will exfiltrate data, then be blocked by the policy, as the attacker can choose a website outside the CSP whitelist. Furthermore, by adding a SecurityPolicyViolation event listener the attacker can inspect the blocked URI in the violation. To send a response, evil.com would redirect the request to a subdomain like <msg>.evil.com.

```javascript
function exfiltrate(data) {
  window.location = "http://evil.com/?d=" + data;
}
```

The main difference between not using navigate-to and using the policy described is that by blocking the navigations, the control is returned to the attacker, allowing for further stealth exfiltration and communication.

3.3.3 Ads leaking data We have found that ads served over HTTPS can still leak the final landing page to a passive network attacker if an ad in the redirection chain is unencrypted. While network-level eavesdropping is outside of CSP’s threat model, the navigate-to directive presents a great opportunity to fix this problem. The problem stems from the fact that when a user clicks on an ad they can be channeled through multiple tracking websites. Listing 1 shows a chain where the user is redirected to three different websites before the landing page. We performed a small empirical study using the same dataset as in Section 6. We extracted all iframes and compared their source URL to a list of known advertisement platforms, e.g. DoubleClick. If the URL matched we followed it and recorded the redirects. This resulted in 24650 unique ads, of which 26.7% have a website between the advertisement platform and the landing page. This highlights the need for advertisement platforms to consider potential violations from tracking websites and further motivates the need for the navigate-to directive.

```plaintext
Listing 1: Example of an ad chain containing three different unencrypted domains between the encrypted ad platform and landing page.
```

As can be seen in Listing 1, both the first and last websites use HTTPS but there exist sites between that are unencrypted. This is very hard for a user to detect as both the ad and the landing page seems secure. The problem with having HTTP in the chain is that an eavesdropper can follow the request and find the landing page.

Our empirical experiments show 10.6% of the ads follow this pattern. As ads become more personal this becomes a privacy concern. Advertisements related to economic status or specific diseases might be leaked without the user’s knowledge.

4 Countermeasures

This section presents countermeasures to the vulnerabilities in 3. The countermeasures cover the specification, mitigations for web developers, as well as, implementation improvements in web browsers. Similarly to the vulnerabilities in Section 3 we distinguish specification- and implementation-level countermeasures.

4.1 Specification

4.1.1 Resource probing Previous login detection methods have forced web developers to rewrite their applications to avoid special types of redirections. As mentioned in [13], Google added an extra regex check to make sure the redirection did not lead to resources that could be loaded cross-origin, e.g. “jpg”, “js” and “ico”.

The navigate-to policy circumvents this by being able to block and report different paths in the URL, i.e. it is possible to block example.com/settings/ and allow example.com/login/. In this case, if /settings/ redirects to /login/ for unauthenticated users, then the CSP report log can be inspected to discern between authenticated and unauthenticated users.

1. https://www.googleadservices.com/...
2. http://www.kozyfj.com/...
3. http://c.j.dotoni.com/...
4. http://www.enjcd.com/...
5. https://<landing page>/*
To fix this, path precision could be removed from the policy. If an origin as a whole can not be trusted, it seems to add little security to trust certain paths on the origin. Since these vulnerabilities affect websites that do not use navigate-to, we also present countermeasures web developers can implement. We recommend avoiding redirection based on secrets. Instead, by showing an error page or rendering the login form on the same page the website is guaranteed to not leak any data, as there will be no redirections. If redirection is necessary, encoding paths in GET parameters, e.g. from example.com/files/to example.com/?path= files/, also mitigates the problem.

4.1.2 Google Search profiling For vulnerabilities like Google Search profiling, as presented in Section 3.2.2, the key countermeasure is to avoid open redirects [46]. One possible way for Google to accomplish this without removing the I’m feeling lucky function is to use a CSRF token [47].

4.1.3 Third-party cookie bypass The navigation path through the redirection chain can depend on the user’s cookies. For this reason, it is not possible to block cookies while checking if the navigation is allowed. Instead, we suggest that cookies attained during the check are temporarily sandboxed and then removed if the navigation is blocked.

4.2 Implementation

4.2.1 History sniffing Privacy problems related to HTTP Strict Transport Security (HSTS) [22] has been researched before [44]. However, they focused on tracking mechanisms similar to cookies but harder to remove.

The solution is to ensure that an attacker can not differentiate between the paths in Figure 3. Again, it becomes the web developers responsibility to either use an internal redirect or not redirect on post data.

4.2.2 Data exfiltration What makes this attack extra powerful is its ability to regain execution control after the navigation fails. It is not specified what should happen when the navigate-to policy blocks a navigation attempt. Currently, Chrome seems to simulate a 204 response [58], resulting in the continuation of the script, and the possibility to exfiltrate more data. Firefox, on the other hand, uses a full-page error that unloads the original document. By using this strategy the script will stop executing, blocking further exfiltration. The attack can also be mitigated by avoiding unsafe-allow-redirects, as this will block the exfiltration during the pre-navigation check.

4.2.3 Ads leaking data The navigate-to directive could block redirect chains which contain HTTPS websites. Currently, the policy navigate-to https: allows navigation to any website using HTTPS. However, combined with unsafe-allow-redirects HTTPS is allowed in the chain, as long as the landing page is HTTPS. One solution is to add a value unsafe-allow-https-redirects which would only allow redirection by HTTPS. A more general solution is to split the policy into navigate-to and navigate-by, where the latter would apply as long as the request is redirected. When no redirect is received, the landing page is checked against the navigate-to policy. By using this method, the following policy would allow any HTTPS redirections which lead to https://example.com.

5 AutoNav

We present AutoNav, an automatic mechanism to aid web developers in inferring policies for their websites. The mechanism crawls the website and creates a map of where pages can navigate. This mapping is used to generate and simplify the policies. AutoNav can generate both per-page policies, where each page on a website gets its own policy, and origin-wide policies [59].

5.1 Inference

We use a key-value map from the crawler to infer the policies. The page is used as a key, and a list of all possible navigations from the page is used as a value. Listing 2 shows an example.

```
1 \{
2   "example.com/a.html": [facebook.com, google.com],
3   "example.com/b.html": [twitter.com, google.com]
4 \}
```

Listing 2: Example of a key-value map generate from crawling two pages on example.com

Using the key-value map, AutoNav can generate separate policies for each page on the website. This is shown in Listing 3. AutoNav can also generate an origin-wide policy based on the union of all the URLs, as shown in Listing 4. These policies are then simplified, using the method described in Section 5.2, to reduce the size and improve maintainability.

```
1 \{
2   "a.html": "navigate-to facebook.com google.com",
3   "b.html": "navigate-to twitter.com google.com"
4 \}
```

Listing 3: Per-page policies generated from Listing 2.

```
1 \{
2   "": "navigate-to facebook.com twitter.com google.com"
3 \}
```

Listing 4: Origin-wide policy generated from Listing 2.

5.2 Policy generation

The navigation policy is a whitelist of URLs that the user is allowed to navigate to. In the most secure setting, the policy should contain the full URLs to each allowed target. While secure, this creates big and hard to maintain lists of URLs requiring much bandwidth. Take Wikipedia for example, their policy could consist of all subdomains like en.wikipedia.org, es.wikipedia.org, etc. for each language. A more compact policy is *.wikipedia.org. This simplification results in both less data being transmitted and a more maintainable policy, however, it does decrease security as it also allows evil.wikipedia.org.

AutoNav supplies developers with best-effort policies that aim to help them harden their websites. Using our parameterized simplification algorithm, developers get a slider style method for finding a trade-off between maintainability, performance and security. The simplification algorithm looks for evidence that all subdomains are trusted. The two sources used are the number of URLs that point to the subdomains (denoted t1) and the number of subdomains that are pointed to (denoted t2). The motivation for t2 is that even if multiple links are found to a.example.com it does not imply...
that b.example.com should be allowed. Similarly, \( t_1 \) is motivated by the notion that the more URLs that point to *.example.com, the more it can be trusted. Figure 4 shows the tree representation of 10 URLs pointing to example.com and its subdomains. \( u_t \) in the figure represents one URL, e.g. \( u_7 \) points to a resource on test.b.example.com. Furthermore, the figure also includes tuples of the threshold values \((t_1, t_2)\). Figure 5 shows the tree after simplification using a threshold of \((2, 2)\). Using this method the policy will only contain 3 entries instead of 7 entries.

Figure 6 shows the result from crawling five pages on ebay.com and generating a policy. The crawler was only supplied with the start page and then found the other four using the crawling algorithm from Section 5.3. The five pages crawled are shown in the middle of the figure in grey with integer labels. The arrows from these nodes indicate that a possible navigation was found between two nodes. The colors correspond to which part of the policy covers the navigation. As shown, *.ebay.com covers a lot of the subdomains, thus they all share the same color. Using the figure, an origin policy could be generated by taking the union of all the colors.

This method of generating policies guarantees that the functionality of the website will remain intact. This is because, if a domain is in the list of possible navigations, then it will be included in the policy. Similar to other policies, the generated policy would need to be recalculated if the website was updated to include new possible navigations. For security, the method guarantees that if a domain is not in the list, then it will not be added to the policy. However, subdomains of domains in the list can be added to the policy.

5.3 Crawling

Our implementation of AutoNav uses selenium with a Chrome instance to crawl the pages on a website. By only supplying AutoNav with the first URL it will automatically collect and crawl new URLs that it finds. When a URL from the same website is found it is added to a set of unvisited URLs, from which the next URL is picked. For each page on a domain, all the JavaScript is executed, then the URLs from links and forms are saved. When the crawling session is over, the inference method described in Section 5.1 is used to generate the policy.

5.4 Limitations

We did not take special care to crawl behind the login. However, it is trivial for a site owner to add a session cookie to the crawler. The more pages AutoNav can crawl the more the policy will cover. Crawling too few pages will result in an incomplete yet secure policy. The policy is secure because AutoNav will never add a domain to the policy that has not been seen.

We use static links to infer the policies, which will miss possible redirections. While not a security concern, we would produce more precise policies if each link was followed dynamically and the redirections recorded.

User-agent sniffing is a common problem for crawling studies. Since the AutoNav is designed for developers we think they can manually add entries like languages.mysite.org and use the AutoNav to detect everything else.

6 Empirical Study

This section presents an empirical study to evaluate the performance impact of the new directive, as well as, how different delivery methods and simplifications can reduce the impact. Next, we evaluate AutoNav in how well automatically generated policies based on a subset of the website cover the full website.

To test how the new navigate-to policy will function on common websites we utilize AutoNav in a crawling experiment. For calculating the performance impact in Section 6.1, we use Alexa’s top 10,000 websites. For evaluating AutoNav itself we use Alexa’s top 14,000, ensuring we have 10,000 domains which all have more than 100 pages each.

6.1 Policy tradeoffs

This section presents the performance tradeoffs between per-page and origin-wide policies together with the delivery methods of HTTP headers and origin policy.

The costs in Table 3 are based on a user visiting \( n \) pages on a website, thus the cost of HTTP headers need aggregation over all pages, i.e. \( \sum_{i \leq n} \). The cost of sending a single CSP policy depends on the number of URLs it contains. We defined the cost of the policy based on the set of URLs, i.e. \( |U_i|, U_i \) being the set of URLs on page \( i \). Further, we can define a set of all URLs as the union of the sets of URLs on each page as \( \bigcup_{i \leq n} U_j \), with corresponding

Figure 4: Tree representation of 10 URLs collected from example.com and its subdomains. The tuples corresponds to the \((t_1, t_2)\) thresholds.

Figure 5: Result of applying the simplification algorithm, using a threshold of \((2, 2)\), to the tree in Figure 4. Resulting in the following policy, navigate-to example.com www.example.com *.www.example.com.

Figure 6: Result from crawling five pages on ebay.com and generating a policy. The crawler was only supplied with the start page and then found the other four using the crawling algorithm from Section 5.3. The five pages crawled are shown in the middle of the figure in grey with integer labels. The arrows from these nodes indicate that a possible navigation was found between two nodes.
Empirical performance Based on the 10,000 crawled domains, a per-page policy, without any simplifications, would increase the header size with 215 bytes, per response. A more maintainable origin-wide policy results in a size increase to 1904 bytes. This cost can be decreased by using the origin policy for delivery, in which case the user only downloads the policy once. Note, as shown in Table 3, that an origin policy outperforms a per-page policy after only 9 responses. While per-page policies might seem better, they are difficult to use since they require knowledge about the content on each page. As such, some websites, e.g. Facebook, use origin-wide policies, motivating the need for an origin policy delivery method.

In addition to the comparison between per-page and origin policy, we also evaluated the cost benefits of using our policy simplification algorithm. Using maximum simplifications, i.e. $t_1 = 1, t_2 = 1$, the average size of the origin wide policy decreases from 1904 to 1004 bytes, a decrease of 47%. Similarly, the per-page policy decreases from 215 bytes to 129 bytes, which is a 40% decrease. For some websites, the benefit of simplification is much greater. In particular, this is the case when websites allow navigation to numerous subdomains. For example, spravker.ru would require a 20438 byte origin policy without simplification, but only 61 bytes after simplification. The big difference stems from the fact that spravker.ru have 954 subdomains.

Table 3: Empirical costs for different policy models.

|        | HTTP  | Origin Policy |
|--------|-------|---------------|
| Per-page | $\sum_{i=1}^{n} 215$ | -             |
| Origin-wide | $\sum_{i=1}^{n} 1904$ | 1904          |

We also performed a more in-depth analysis of three websites, ebay.com, wikipedia.org and stackexchange.com, to see how the threshold affect performance. Fixing $t_1$ to 0, we only focus on the number of subdomains when deciding if wildcards should be used. Figure 7 shows these domains as solid lines, together with the corresponding costs for their origin policies. As can be noted, after the $t_2$ threshold reaches 280 subdomains Wikipedia can no longer use the wildcard and the policy quickly increases in size. By increasing $t_1$ to 1000, more URLs are required before simplifications can take place. As can be seen in the dashed lines in Figure 7, the crawled data from Wikipedia did not contain enough URLs to the same domain for a simplification. This would be the desired behavior if Wikipedia required high assurance before introducing wildcards.
6.2 Coverage

While full coverage may be desirable, the goal of AutoNav is to help even if the coverage is not complete, by providing a useful baseline policy for developers to build on.

Our coverage was generated similarly to the method used in CSPAutoGen [37]. We generate the policy based on a training set of 80% of the pages on a domain and then test how well they match the other 20%. We define \( U \) as the set of URLs in the training set. For the \( n \) pages in the validation set, we check if URLs on the page are covered, i.e. \( p_i \subseteq U \), where \( p_i \) is the set of all the URLs on page \( p_i \). Finally, the coverage of a website is calculated as:

\[
\text{coverage} = \frac{|p \cap U|}{|U|}
\]

Using this formula, \( c \) is calculated for all the websites that were crawled. In total 42% of all the websites were fully covered and for 59% of the websites 95% or more were covered. Note that these results come from only crawling 100 pages, deeper crawls can greatly increase this coverage.

7 Related work

Automatic methods for generating CSP policies have been studied before [12, 16, 18, 37]. deDacota by Doupe et al. [12] performs static analysis of ASP.NET code in order to separate JavaScript code from data. After the JavaScript has been separated into files, a CSP policy was generated for the file. AutoCSP by Fazzini et al. [16] takes a similar approach by analysing server-side code, PHP in this case. However, AutoCSP uses dynamic taint tracking instead of static analysis, allowing it to create policies for inline JavaScript events and CSS code.

While both AutoCSP and deDacota were successful, they required access to the source code. Golubovic’s autoCSP [18] method utilizes a reverse proxy and the report function in CSP to run an application in learning mode. In this mode, the tool externalizes inline code and generates policies for the scripts that should be allowed. A drawback is that autoCSP requires manual navigation through the application to ensure all scripts are triggered. While this works well for scripts, it becomes challenging when all possible links need to be navigated. A similar approach based on the report function in CSP was utilized by King’s Firefox extension Laboratory [30]. Laboratory is impressive as it enables users to record and generate CSP policies in real-time while visiting a website. Starting with a strict policy, it gradually weakens it as violation reports are received. While this method could be extended to include navigations, it would require the user to initiate all possible navigations on each page. Instead of relying on the reporting functionality, our method uses a combination of static and dynamic analysis to record the navigations a document can initiate. By doing this we avoid the problem of having to initiate all navigations to generate a report. We also improve on the manual aspect of traversing a website by implementing an automatic crawler, as suggested by Golubovic, in future works.

CSPAutoGen Pan et al. [37] is also intended to automatize CSP generation. CSPAutoGen uses a crawler to analyze websites and try to infer which scripts should be allowed. Similar scripts are also generalized into abstract syntax trees, based on how many similar scripts are found. Once a policy has been inferred, CSPAutoGen functions as a proxy between the client and the server. This enables CSPAutoGen to rewrite requests and responses in real-time, without needing any CSP configurations on the website. This is a great feature when a server needs to be secured without any direct modification.

While a similar approach could be used for URLs and navigation, our goal is to generate CSP policies that can be used by the server directly.

In addition to policy generation, we benefit from origin-wide policies [59]. Similarly to the work on evaluating general origin-wide policies by Van Acker et al. [50], our results also indicate that an origin-wide policy provides additional security without degrading performance.

8 Conclusion

Security We have performed a security analysis of the emerging CSP directive navigate-to. Our findings show that the current specification and implementations introduce new vulnerabilities. The vulnerabilities include methods for resource probing, login detection, circumventing blocking of third-party cookies, as well as, history enumeration. To mitigate these problems we propose countermeasures to both the specification and implementation of the directive. We demonstrate that the directive triggers vulnerabilities even in websites that do not use the directive in their policies. Thus, we also propose countermeasures web developers can make to their applications in order to mitigate the possibilities of being exploited.

Automatization We have evaluated the possibility of automatically generating policies to help developers adopt the policy. We created AutoNav. AutoNav uses a black-box approach to crawl websites and generate CSP policies that can be directly applied to the website. Our results show that in total 42% of all the websites were fully covered and for 59% of the websites 95% or more were covered. We further simplify the process by identifying categories of websites which the policy better fits. Our research shows that shopping and adult websites are best covered. These websites have a high incentive to keep the users on their site, with the exception of linking to sponsors or partners, which AutoNav’s policies cover.

Performance To analyze the performance of navigate-to we have conducted an empirical study of Alexa’s top 10,000 websites. For each website, we have crawled 100 pages and based on these generated policies. We show that on average this directive would increase the header size by 215 bytes per request. However, using our simplification algorithm we produce more maintainable policies which were also 40% smaller on average. Our results indicate that using an origin policy would require a one time cost of 1904 bytes, or 1004 using simplified policies, as opposed to 215 bytes per request. Thus we show that the performance hit from the increased security can be efficiently mitigated by adopting an origin policy with suitable simplifications.

Coordinated disclosure We are in the process of disclosing the discovered vulnerabilities to the affected vendors, including Google where both Chrome’s implementation of navigate-to directive and the Google Search website are affected. Based on our recommendations Firefox chose to harden their implementation against exfiltration attacks, as explained in Section 4.2.2.
Acknowledgments

Thanks are due to Mike West, Christoph Kerschbaumer, and Daniel Hausknecht for helpful discussions on the topic of navigate-to. This work was partly funded by the Swedish Foundation for Strategic Research (SSF) and the Swedish Research Council (VR).
