Abstract

Understanding emotions that people express during large-scale crises helps inform policy makers and first responders about the emotional states of the population as well as provide emotional support to those who need such support. We present COVIDEMO, a dataset of ~3,000 English tweets labeled with emotions and temporally distributed across 18 months. Our analyses reveal the emotional toll caused by COVID-19, and changes of the social narrative and associated emotions over time. Motivated by the time-sensitive nature of crises and the cost of large-scale annotation efforts, we examine how well large pre-trained language models generalize across domains and timeline in the task of perceived emotion prediction in the context of COVID-19. Our analyses suggest that cross-domain information transfers occur, yet there are still significant gaps. We propose semi-supervised learning as a way to bridge this gap, obtaining significantly better performance using unlabeled data from the target domain. We make our code and data available at https://github.com/tsosea2/CovidEMO

Keywords: Emotion Detection, Covid-19, Twitter

1. Introduction

We live in unprecedented times caused by a coronavirus: the COVID-19 pandemic. This pandemic has forced extremely rapid changes in our daily lives in the push to stem the spread of the COVID-19 virus. Many of us have been uprooted, disrupted and distanced from family, friends and colleagues. We have transitioned in no time into a world that is suddenly more virtual than personal, sacrificing many of the daily rhythms and joys of life. These events coupled with the dramatic lifestyle changes consequently led to vast amounts of data generated on social media platforms such as Twitter. Understanding emotions that people increasingly express on social media during large-scale crises can have wide-ranging implications, from promoting a deeper understanding of the society to informing policy makers and first responders about the emotional states of the population (Dennis et al., 2006; Fraustino et al., 2012). In Natural Language Processing, multiple datasets have been proposed to detect emotions on social media (Mohammad and Kiritchenko, 2015; Volkova and Bachrach, 2016; Abdul-Mageed and Ungar, 2017; Demszy et al., 2020), including from hurricane disasters (Schulz et al., 2013; Desai et al., 2020). Recent studies (Kabir and Madria, 2021; Imran et al., 2020) propose the study of emotions in COVID-19 and introduce various datasets annotated with emotions. However, these datasets are not available to the large public. Moreover, in this paper, we study COVID-19 from a completely different standpoint: We find that the data distribution of COVID tweets diverges substantially from month to month, and emphasize that as time progresses, models constantly need recently streamed training data to remain accurate in their predictions. To this end, we analyze the detection of emotions in COVID from a domain adaptation perspective.

We explore the detection of perceived fine-grained emotion during the COVID-19 pandemic to answer two research questions. First, from a social point of view, each crisis is situated in its own unique social context (Palen and Anderson, 2016), triggering distinct emotions, and impacting different populations in vastly distinct ways. COVID-19 is a crisis that has dominated the world stage and influenced every aspect of human life. What are the emotions expressed through social media, and how do they change over time? Second, from a system point of view, modern data-driven emotion prediction systems are trained on large, annotated datasets. How well can models learn from existing resources since timely annotation of fine-grained emotions can be costly to accumulate as new crises arise, and how well do models generalize as a crisis unfolds through different stages?

To answer these questions, we introduce COVIDEMO, a dataset of ~3K tweets in English annotated with Plutchik-8 emotions (Plutchik, 2001); examples are shown in Table 1. Our dataset provides an ideal test bed to examine how well modern NLP models generalize across domains and crises in the task of perceived emotion prediction. Moreover, COVIDEMO is temporally distributed across 18 months, which enables the exploration of distributional shifts that occurred from the start of the pandemic. Our analysis reveals that the co-occurrence and distribution of emotions are drastically
Please resign, you are the master of misleading who started politicizing the public health crisis. You are a part of the problems the world is facing!

‘Perfect storm’: Haiti COVID-19 peak set to collide with hurricanes. <URL>

The German government is taking all kind of measures to protect its people while the Dutch government does not care about their people #corona

Table 1: Examples from COVIDemo annotated with the Plutchik-8 emotions.

| Emotion | Word      |
|---------|-----------|
| anger   | misleading |
| disgust | who        |
| sadness | started    |
| fear    | politicizing |
| sadness | health     |
| anger   | crisis      |

Different from natural disasters such as hurricanes (Desai et al., 2020). However, while Desai et al. (2020) pointed out that emotion distributions are fairly consistent across hurricanes, in COVIDemo we observe a different phenomenon: as COVID-19 progressed, we note considerable distributional shifts both in the lexical and the emotion label space. Additionally, we found that politically related words are more likely to associate with negative emotions, while vaccine-related words are more likely to associate with positive ones.

We carry out a comprehensive set of experiments that evaluate model generalization under domain shift. Experimenting with large-scale pre-trained language models including BERT (Devlin et al., 2019), BERTweet (Nguyen et al., 2020), and COVID-Twitter-BERT (Muller et al., 2020), we find that directly applying models trained on other emotion datasets to COVIDemo leads to poor overall performance, indicating considerable domain gaps. Our analysis also reveals two surprising findings: 1) Performing direct transfer from a general emotion dataset such as GoEmotions (Demszyk et al., 2020) attains better performance compared to transferring information from a disaster-specialized corpus such as HurricaneEmo (Desai et al., 2020), indicating the vast differences across crises. 2) Besides the inter-domain gaps observed, we note in-domain model performance gaps along the temporal dimension as well. Specifically, we find that training a model on the first 6 months of our data and testing on the last 6 months obtains a 2% decrease in F-1 score compared to using training and testing data from the same timeframe (last six months).

Finally, we investigate methods to bridge both the inter-domain and the in-domain temporal gaps. We motivate the importance of lowering these gaps: first, due to the time-critical, dynamic nature of disasters such as COVID-19, the time needed to acquire labeled data might severely impact the early-risk assessment capabilities of the authorities and slow the relief response. Second, labeling data for every potential disaster is not feasible in terms of annotation costs. To this end, we leverage Noisy Student Training (Xie et al., 2020), a semi-supervised learning technique utilizing the readily available COVID-19 unlabeled data, and the non-COVID labeled data, to obtain a better emotion detection model. This improves the performance of the vanilla models significantly, by 1.5% on average.

We summarize our contributions as follows: 1) We introduce COVIDemo, an emotion corpus containing ~3K tweets streamed during the COVID-19 pandemic, which enables the exploration of model generalization across domains, as well as between different time periods of the same domain. 2) We perform a comprehensive analysis of emotion expression in COVIDemo, indicating various particularities and comparing our corpus with other datasets in the literature. 3) We observe considerable domain gaps and offer potential explanations into why models struggle to transfer information. 4) We bridge these gaps using semi-supervised learning. We will release our data and models upon publication.

2. Data

2.1. Data collection

Preprocessing. We sample 129,820 English tweets from Chen et al.’s (2020) ongoing collection of tweets related to the COVID-19 pandemic, starting from January 2020 until June 2021. Our sampling strategy involves selecting an equal number of tweets each month in the time period mentioned above. The tweets are anonymized by replacing twitter usernames with <USER> and links with <URL>, following Cachola et al. (2018). Additionally, prior work found that even in disaster contexts, the fraction of tweets expressing an emotion is small (Desai et al., 2020), thus annotating randomly sampled tweets would be costly and unproductive. Therefore, we follow their work to obtain tweets that are more likely to contain emotions for annotation. Concretely, we ensure that each tweet encompasses at least one word from EmoLex (Mohammad and Turney, 2013), a lexicon of ~10K words in various languages annotated with emotion labels. After this filtering process, we obtain 89,274 tweets. As stated in Desai et al. (2020), this filtering is soft, i.e., does not filter out tweets with weak or implicit emotions.

Annotation and quality control. We randomly sample 5,500 tweets from this data and use Amazon Mechanical Turk to crowdsource Plutchik-8 emotions: anger, anticipation, joy, trust, fear, surprise, sadness, disgust. We allow multiple selection, as well as a none of the above option in case no emotion is perceived. During the annotation process, we determine the inter-annotator agreement using the Plutchik Emotion Agreement (PEA) metric that takes into account emotion proximity on the Plutchik wheel (Desai et al., 2020).

We use a qualification process for quality control and training. Specifically, two members of our research

1 We use the Twarc software to obtain the tweet texts, and FastText (Joulin et al., 2017) for language identification.
Table 2: Content words and hashtags most associated with each Plutchik-8 emotion.

| Emotion | Content words/Hashtags |
|---------|-------------------------|
| disgust | Content words: disgusting, fucking, million, trump, dead, shit, president, america, china, done |
| anger   | Content words: fuck, evil, bullshit, stupid, idiot, damn, obama, church, lying |
| fear    | Content words: scared, exam, dangerous, infected, confirmed, worse, sir, wuhan, risk, rate |
| sadness | Content words: sad, cry, died, suffering, toll, record, sorry, feel, tested, facing |
| anticipation | Content words: effort, christmas, available, join, start, future, vaccination, vaccinated, coming, open |
| trust | Content words: working, support, safe, help, say, being, world, vaccine, good, more |
| joy | Content words: grateful, beautiful, thanks, happy, love, great, little, morning, good |
| surprise | Content words: believe, year, lockdown, new, china, virus, day, america, covid19, get |

Figure 1: Emotion distribution of two types of crises: hurricanes and the COVID-19 pandemic.

We also show emotion distribution across time in Figure 2 obtained grouping the tweets by quarter (e.g., Q1-2020 encompasses the first three months of 2020). We observe that the label distribution varies significantly from quarter to quarter, denoting potential changes in the discussion topics or the overall feelings of the masses. Notably, we note proportion variations as high as 12% in consecutive quarters. For instance, the proportion of the sadness emotion increases by as much as 12% in the second quarter of 2020 compared to the first quarter. Moreover, we see the opposite trend in the fear emotion, whose proportion decreases by 10% percent. One potential explanation could be that the first shock that COVID-19 produced enacted fear into people (Q1 2020). However, as people started to get accustomed to the lockdown, the fear slowly turned into sadness.
Emotion co-occurrence. Figure 3 depicts how emotions co-occur with one another in COVIDEMO. For each emotion pair, we compute the Pearson correlation coefficient. Overall, we observe stronger correlation between emotions in the same positive/negative categories. For example, (anger, disgust) and (sadness, fear) appear much more frequently than (anger, anticipation) and (anger, joy). Table 1 shows samples from COVIDEMO with multiple emotions perceived. Notably, in many cases lexical cues alone cannot account for the emotions, as evident in the second example. Although the word “perfect” suggest optimism, the annotations are nowhere near positive. In the third tweet, there is a co-occurrence of polarizing emotion because the tweet deals with a positive and a negative situation at the same time.

Lexical analysis. To understand better what topics or events are associated with each emotion, we perform a lexical analysis to examine the co-occurrence between content words (nouns, verbs, adjectives and adverbs), hashtags and perceived emotions. In particular, we calculate the log odds ratio \( \log\left( \frac{P(w|e)}{P(w|\neg e)} \right) \) (Nye and Nenkova, 2015) with a frequency threshold of 10 for lemmatized content words and 2 for hashtags. Table 2 shows the highest ranked content words and hashtags for each emotion category. We notice that politically or country-oriented words are more likely to associate with negative emotions (president, america, china), while vaccine-related words are more likely to associate with positive emotions.

2.3. Benchmark Dataset

To enhance reproducibility and aid the progress on understanding the expression of emotion in the COVID-19 context, we use COVIDEMO as a benchmark dataset for perceived emotions. We split our data into a development and testing split, as shown in Table 3. We also note that the data is evenly distributed across the time axis, with an equal number of 158 tweets for each of the 18 months that our dataset spans. As mentioned previously, disasters are time-critical events, and since our goal is to examine the emergence of such disasters, we mainly focus on domain adaptation techniques, hence we omit creating a training set.

3. Domain Transfer Assessment

Using COVIDEMO, we evaluate the ability of modern NLP models to transfer information from existing sources with annotated emotions in an inter-domain setting for perceived emotion detection, and if models generalize temporally in the same larger context (in-domain temporal transfer).

3.1. Our Framework

We consider a dataset \( D \) labeled with emotions, and another collection of labeled examples \( T \) from a different domain. We aim to assess how well large pre-trained language models can transfer information from the domain of \( D \) to the domain of \( T \). To this end, we train our models on \( D \), then evaluate the performance on the test set of \( T \). In our framework, \( D \) is COVIDEMO for the inter-domain experiments, or a temporal slice of COVIDEMO for the temporal experiments. Due to the uneven label distribution and the multi-label nature of the data, we develop binary classifiers for each emotion following Desai et al. (2020).

Methods. Motivated by the tremendous success of large pre-trained masked language models, we use the following models: 1) BERT (Devlin et al., 2019) base uncased model trained on Wikipedia and BookCorpus (Zhu et al., 2015), 2) BertTweet (Nguyen et al., 2020) model trained on 850M english tweets, and 3) COVID-Twitter-BERT (CT-BERT) (Müller et al., 2020) trained on 97M tweets. Additionally, we also employ a basic lexicon-based classification approach, 4) EmoLex (Mohammad and Turney, 2013) is the word-associated lexicon mentioned previously in the paper. In this approach, if a tweet contains a word annotated with an emotion \( e \) in EmoLex, then we assign \( e \) as a label for the tweet.

Experimental setup. We perform all our experiments on an Nvidia P100 GPU. To report the performance, we average the F-1s of 5 different runs and re-
support the average value. In all our experiments, we found that a batch size of 16 and a learning rate of $5 \times 10^{-5}$ works well.

### 3.2. Inter-domain Transfer

Our first domain transfer assessment explores how well emotion detection models trained outside our domain generalize to the COVID context. We consider two well-established datasets for training. First, we experiment with GoEmotions (Demszky et al., 2020), a dataset from the general Reddit domain annotated with 28 emotions and the neutral class. The emotion space in GoEmotions differs slightly from our Plutchik-8 setup, hence we perform a mapping between the emotions in GoEmotions and the Plutchik-8 emotions. Second, we use HurricaneEmo (Desai et al., 2020), a Twitter dataset collected from natural disasters such as hurricanes and labeled with fine-grained emotions. HurricaneEmo provides Plutchik-8 labels.

**Results.** We show the results obtained in Table 4. Here, we denote by $M$-$DS$ the model $M$ trained on dataset $DS$ and tested on COVIDEMO. We emphasize a surprising finding: models trained on a general domain (GoEmotions) generalize better on COVIDEMO compared to models trained on natural disasters such as hurricanes (HurricaneEmo). In fact, the performance gaps between GoEmotions and HurricaneEmo are vast, and we see as much as 0.20 differences in average macro F-1. At the same time, we note that our basic lexicon-based Emolex approach outperforms the HurricaneEmo transfer models. This result hints to a sizeable divergence between crises such as hurricanes and COVID-19. The CT-BERT model improves the performance by 1% on average (with statistical significance), compared to BERTweet which only obtained marginal improvements. Although both are trained on Twitter data, we postulate that CT-BERT likely benefited from COVID-related biases that the model manages to leverage.

### 3.3. In-domain Temporal Transfer

COVIDEMO spans a large period of time (18 months) marked by substantial narrative shifts in the society. Thus we investigate potential distributional shifts across the temporal dimension. Specifically, we aim to analyze how well models trained on past COVID-19 data generalize to a fresh batch of new data. To this end, we stage the following setup: First, we accumulate the subsets $F$ and $L$ corresponding to the initial six months and the last six months respectively. Denoting the development and test sets of COVIDEMO as $C_{tr}$ and $C_{ts}$, we create additional sets $L_{tr} = L \cap C_{tr}$ and $L_{ts} = L \cap C_{ts}$. Additionally, we randomly sub-sample $F_{tr} \subset F$ such that $|F_{tr}| = |L_{tr}|$, where $|.|$ denotes the size of a set. In this setting, we compare training on $F_{tr}$ and testing on $L_{ts}$ vs. training on $L_{tr}$ and testing on $L_{ts}$. In other words, we investigate whether model performance on COVIDEMO decreases as time passes. Here we experiment with CT-BERT (Müller et al., 2020) (since it achieved better performance in Section 3.2).

**Results.** Table 5 shows that the models trained on the same time period as the testing data outperforms the model trained on a different timeframe.
revealed that the label distribution and topics discussed in-domain temporal gaps

In Section 2.2, we re-

there are large gaps in performance between Hurrica-

These findings could also explain why wide impact COVID-19 has had and a more social na-

domain than a natural disaster one, likely due to the context is significantly more correlated with a general

insights can spur further research into bridging these gaps. In Section 5, we propose semi-supervised learn-

ings hint that although HurricaneEmo is closer to GoEmotions compared to COVID-19. These find-

HurricaneEmo distribution diverges even more from GoEmotions (~60K). Table 6 shows the cosine similarity and the Jensen-Shannon divergence for the frequency distribution of all content words (lower-cased and lemmatized) across the three datasets. Interestingly, the COVIDEMO distribution is significantly closer to GoEmotions compared to HurricaneEmo: the cosine similarity is substantially lower (0.243 vs. 0.346) while the divergence is larger (0.312 vs. 0.351). Moreover, the HurricaneEmo distribution diverges even more from GoEmotions compared to COVID-19. These findings hint that although HurricaneEmo is closer to COVIDEMO than to a general domain, the COVID-19 context is significantly more correlated with a general domain than a natural disaster one, likely due to the wide impact COVID-19 has had and a more social nature of the crisis. These findings could also explain why there are large gaps in performance between HurricaneEmo and GoEmotions transfers.

In-domain temporal gaps In Section 2.2 we re-

Table 6: Cosine similarities and Jensen-Shannon divergence of word distributions between GoEmotions (Demszky et al., 2020), HurricaneEmo (Desai et al., 2020), and COVIDEMO.

|                      | Cosine Similarity |                | Jensen-Shannon Divergence |
|----------------------|-------------------|----------------|--------------------------|
|                      | COVID             | GoEMOTIONS     | HURRICANEEMO             | COVID | GoEMOTIONS | HURRICANEEMO |
| COVID                | 1.0               | 0.346          | 0.243                    | 0.0   | 0.312      | 0.0          |
| GoEMOTIONS           | 1.0               | 0.346          | 0.243                    | 0.0   | 0.351      | 0.374        |
| HURRICANEEMO         | 1.0               | 1.0            |                          | 0.0   | 0.374      | 0.0          |

Figure 4: Cosine similarities and Jensen-Shannon divergence between the first month of COVID-19 and each subsequent month.

during COVID-19 has shifted over time. To consolidate these analyses, we carry out an additional experiment that captures distributional shifts in vocabulary. In Figure 4, we show the cosine similarities and Jensen-Shannon divergence for the frequency distributions of content words (lower-cased and lemmatized) for unlabeled tweets spanning the 18 months in our data. As time passes, we observe a constant shift in the lexical distribution of the tweets. Concretely, while the cosine similarity between the first and the second month of COVID-19 is 0.97, by the end of the 18th month this value decreases significantly, getting as low as 0.63. We observe the same phenomenon in the divergence of the distributions as well. These findings emphasize the considerable temporal gaps found in long-lasting disasters such as COVID-19, and that temporal slices of the tweets can diverge significantly even though they originate from the same domain.

5. Bridging the Gaps Between Domains

As crises such as COVID-19 strike, large amounts of user-generated content are produced on social sites. However, due to the nature of disasters unfolding rapidly, the high costs needed for annotation, and the considerable distributional changes along the time axis, immediately obtaining labeled data from the ongoing disaster might prove infeasible. However, rapid understanding of such events is critical for rapid risk assessment and effective resource allocations. Therefore, we cannot rely on obtaining large quantities of labeled data, and we require effective domain adaptation techniques which can leverage labeled data from outside the disaster domain. However, we emphasized previously that models typically have a hard time effectively transferring information for emotion detection. We ar-

**significantly**, obtaining a Macro F-1 increase of 3.3% on average. Notably, we observe improvements as high as 7.6% in F-1 on joy and 14.6% on anticipation. Intu-

itively, since the model is trained on the same temporal distribution as the test set, and anticipation is closely re-

lated to ongoing events (i.e., people usually anticipate certain events), it is extremely probable that the model has been trained on similar events in the training set, so the model easily recognizes the emotion.
Table 7: Macro F-1 scores using inter-domain adaptation (first block), in-domain temporal adaption (second block), and of our best performing models using Noisy Student training (Xie et al., 2020). We assert significance† if p < 0.05 under a paired-t test with base model (CTBERT-GOEMOTIONS for inter-domain transfers and CBTERT-$F_{tr}$ for temporal transfers.)

| MODEL           | ANG | ANT | DIS | FEA | JOY | SAD | SUR | TRU | AVG  |
|-----------------|-----|-----|-----|-----|-----|-----|-----|-----|------|

| CBTERT-$L_{tr}$ | 0.769 | 0.631 | 0.498 | 0.668 | 0.781 | 0.724 | 0.493 | 0.502 | 0.633† |

Method

Noisy Student training (Xie et al., 2020) leverages knowledge distillation (KD) and self-training to iteratively train two models in a teacher-student framework. The framework trains the student in traditional KD fashion, matching its predictions to those of the teacher. Concretely, the training loss on unlabeled examples is:

$$\mathcal{L} = \sum_{x \in U} l(f_\tau(x), f_\tau^{\text{noised}}(x)),\$$

where $U$ is the set of unlabeled examples, $l$ is the cross-entropy loss, and $f_\tau$ and $f_\tau'$ are the teacher and the student models, respectively. We note one vital particularity of this framework: The student is trained using noised input examples. In the original paper, the authors also use a larger network for the student, but we noticed here that using equal-sized architectures works well enough. Leveraged noised inputs, Noisy Student exposes the student to more difficult learning environments, and usually leads to an increased performance compared to the teacher. To add noise to our input examples, we use two approaches: a) Synonym replacement: We replace between one and three words in a tweet with its synonym using the WordNet English lexical database (Fellbaum, 2012). b) Back-translation: We use back-translation and experiment with different levels of noise corresponding to different translation chain lengths (e.g., English-French-Spanish-English). Smaller chain lengths lead to less noise, while increasing the length of the chain produces examples with significantly more noise. For each unlabeled example, we sample uniformly a chain length in the range 1-60, and use the following languages for translation: Russian, French, Spanish, Italian, and German.

A vital aspect of our framework, however, is that in our experiments we use unlabeled data from COVID-19. Concretely, in the inter-domain adaptation experiments, where we aim to transfer information from GoEmotions to COVIDEMO, we use labeled data from GoEmotions alongside unlabeled data from COVIDEMO (we make sure the model does not see any example from the test set). In the temporal setup, where we train on the first six months $F_{tr}$ and test on the last six $F_{ts}$, we use $F_{tr}$ in conjunction with unlabeled data generated in the last six months.

Results.

We show the results obtained using Noisy Student training in Table 7. Our SSL technique bridges both the inter-domain and the in-domain temporal performance gaps. First, we note that our SSL-powered CT-BERT model trained on GoEmotions outperforms the plain CT-BERT by as much as 1% in average macro F-1. Moreover, in our temporal transfer experiments, Noisy Student improves the performance of the model by 1.7%. These results are statistically significant, and emphasize that our method obtains better generalization performance and can be leveraged to produce better domain adaptation models.

6. Related Work

Emotion datasets.

Emotion detection has been studied extensively with applications in music (Strapparava et al., 2012), social networks (Mohammad, 2012; Islam et al., 2019), online news (Bao et al., 2009), health communities (Sosea and Caragea, 2020; Khanpour and Caragea, 2018; Khanpour et al., 2018; Biyani et al., 2014), and literature (Liu et al., 2019). All these domains can be examined with the help of large curated datasets. These datasets are created using automated approaches such as distant supervision (Wang et al., 2012; Abdul-Mageed and Ungar, 2017), while others are manually labeled using crowdsourcing (Aman and Szpakowicz, 2007; Poria et al., 2019; Liu et al., 2019; Sosea and Caragea, 2020; Demszky et al., 2020; Desai et al., 2020). In this work, we resort to the latter and create COVIDEMO, a dataset of 2, 847 tweets annotated with the Plutchik-8 emotions.

Emotions detection methods.

In the early stages of emotion detection, most approaches used feature-based methods, which usually leveraged hand-crafted lexicons, such as EmoLex (Mohammad and Turney, 2013) or the Valence Arousal Lexicon (Mohammad, 2018). These features were subsequently used to build classifiers such as Logistic Regression or SVMs. However,
due to the recent advancements in deep learning as well as large pre-trained language models, all state-of-the-art approaches (Sosea and Caragea, 2021; Desai et al., 2020; Sosea and Caragea, 2020; Demszky et al., 2020) employ BERT-based (Devlin et al., 2019) classifiers.

**COVID-19 emotion analysis.** Since the emergence of the pandemic, numerous studies have been carried out on social media networks to understand COVID-19 and its effects on the larger population. Ils et al. (2021) annotated 2.3K German and English tweets for the expression of solidarity and used it to carry out an analysis into the expression of solidarity over time. On the other hand, Saakyan et al. (2021) annotated a dataset for detecting general misinformation in the pandemic. Sentiment analysis and emotion detection on social media during COVID-19 have seen tremendous popularity as well [Beck et al., 2021] [Kabir and Madria, 2021] [Adikari et al., 2021] [Choudrie et al., 2021] [Scarpina, 2020] [Calbi et al., 2021] due to the ability to provide vital information into the social aspects and the overall dynamics of the population. In this paper, however, we annotate COVIDemo, a dataset of fine-grained emotions and employ a comprehensive analysis into cross-domain and temporal generalization of large pretrained language models. We will make the dataset available to the large public.

**7. Conclusion**

We present COVIDemo, a dataset of tweets annotated with perceived Plutchik-8 emotions. Using this dataset, we reveal emotion distributions and associations that are distinctive from prior studies on disaster-related emotion annotation and detection. We further show that models trained on other emotion datasets transfer poorly. Additionally, we indicate that models transfer poorly when trained on different temporal slices of an event such as COVID-19. Next, we conduct a comprehensive analysis of the temporal and inter-domain gaps to offer a better understanding of why models transfer poorly. As a potential solution to bridge these gaps and offer a more reliable disaster response, we leverage the large amount of readily available data alongside semi-supervised learning techniques.
